Preface

This handbook contains a unique collection of chapters written by the world's leading researchers in the dynamic field of Consumer Psychology. Although these researchers are housed in different academic departments (i.e., marketing, psychology, advertising, communications), all have the common goal of attaining a better scientific understanding of cognitive, affective, and behavioral responses to products and services, the marketing of these products and services, and societal and ethical concerns associated with marketing processes. Consumer Psychology is a discipline at the interface of Marketing, Advertising, and Psychology. Work in Consumer Psychology integrates theories and methods from many different areas and many different approaches to research and practice. Consumer Psychology research focuses on fundamental psychological processes as well as on issues associated with the use of theoretical principles in applied contexts.

Our vision for the *Handbook of Consumer Psychology* was to bring together distinguished researchers from a variety of academic backgrounds to provide succinct summaries of state-of-the-art research as well as to provide a place for authors to speculate and provide suggestions for future research and practice. The chapters present theoretical frameworks that address a broad range of important well-established phenomena in addition to suggestions that will serve as a guide for future research on yet-to-be-discovered phenomena and practices. We were delighted that all of the researchers we contacted agreed that the discipline needed such a resource and that they were willing to write chapters for the *Handbook*.

The first chapter provides a history of the field of consumer psychology from 1895 to 1960. The remaining chapters are organized around seven themes. The first theme focuses on the dominant consumer information processing paradigm that specifies how product information is perceived, comprehended, interpreted, retained, and used. The second organizing theme centers on motivation, affect, and consumer decisions. These chapters focus on variables that energize consumers to buy and to consume. The next section examines the important topics of persuasion, attitudes, and social influence. These chapters describe principles that serve as the basis for understanding and influencing change in consumer beliefs, attitudes, and behaviors. The following theme, behavioral decision research, focuses on key factors that influence consumer choice. The next theme examines products, preferences, places, and people. This section covers topics such as aesthetics, branding, and retailing. The penultimate section focuses on consumer well-being, and the final section focuses on research methods. Together, these chapters provide a broad and integrative perspective on the field of consumer psychology.

While this edition of the *Handbook* covers many areas of research, it is by no means comprehensive or complete. Just as has been the case for the *Handbook of Social Psychology*, as new research, frameworks, and controversies develop, we plan on providing updates, revisions and extensions to the material in this *Handbook* in the coming years. We hope that the current *Handbook* contributions stimulate excitement and discussion about the topics and that the readers will contribute to the discipline of consumer psychology through their own teaching, research, and practice. This *Handbook* will be of interest to well-established academics and practitioners as well graduate students and individuals just beginning careers as academicians or practitioners. Consumer Psychology is truly an interdisciplinary field, and we are pleased to have the opportunity to provide a forum for the viewpoints of contributors to the discipline. It has been a pleasure to work with enthusiastic contributors and publishers!

INTRODUCTION

The field of consumer psychology is alive and well. A review of recent issues of the *Journal of Consumer Research*, the *Journal of Consumer Psychology*, and other major publication outlets reveals continued high levels of interest and research activity on a widening array of basic and applied research topics. Contemporary consumer psychologists can be found in academic departments of advertising, marketing, psychology, human ecology, communications, sociology, anthropology, etc. Consumer psychologists can also be found government agencies, profit and non-profit businesses. Training for work in consumer psychology often consists of coursework and research in multiple areas (Haugtvedt, 2006).

As with most areas of study, the topical focus of contemporary research projects in consumer psychology are not all new. In this chapter, we trace the work of psychologists who can be characterized as pioneers in the field of consumer psychology. Our review is selective and not exhaustive. Our intention is to illustrate how the training, creativity, and motivation of early researchers provided a significant part of the foundation of the field as we know it today and as reflected by chapters in this volume.

Our review focuses on the years between 1895 and 1955. The activities in this time frame set the stage for two major events in the 1960s. One major event was the establishment of Consumer Psychology Division (Division 23) of the American Psychological Association in 1960. In the late 1950s, a conflict over ownership of the discipline took place within the American Psychological Association leading to the establishment of a society of practitioners and academics with sole interest in the psychological response of the consumer. A brief history of this conflict appears at the end of this chapter. The second major event was the publication of three widely recognized textbooks on the topic of consumer behavior. Books by Francesco Nicosia (1966), John Howard and Jagdish

Sheth (1965), and James Engel, David Kollat and Roger Blackwell (1968) each contained a comprehensive model of important constructs underlying consumer behavior.

Early pioneers of consumer psychology were influenced greatly by their training. Prominent perspectives included the mentalist approach (represented by experimental psychologists such as Wundt, James, and Titchener); the behavioral or mechanistic approach (represented by Watson and Thorndike); and the dynamic psychology approach (represented by Freud and McDougall). Early applied psychologists often had to hide their interest and research in consumer psychology from some of the leaders of the parent discipline because these leaders felt that the field of psychology had to mature before applications to the business world could be espoused. As will be reviewed, much of the work of these early consumer psychologists focused on responses to advertising. This, however, led to other concerns as consumer psychologists of the time were not well accepted by the professional advertising community. The practitioners viewed the psychologists as interfering in their work and felt that the scientific approaches were irrelevant. All of this changed in the early 1900s.

It is important to note that the label “consumer psychology” did not exist during this time period. Rather, work that explored the application of psychological principles to business activity was known simply as “applied psychology” and the proponents were “applied psychologists.” The first contributions to what would be characterized as “consumer psychology” occurred within what was termed “scientific advertising,” followed closely by the scientific study of personal selling. These early pioneers eventually established a home under the parent applied discipline of industrial psychology which became identified as Division 14 of the American Psychological Association. Use of the term “consumer psychology” did not appear until the late 1950s.

THE HISTORICAL CONTEXT LEADING TO THE ADVENT OF CONSUMER PSYCHOLOGY

Our 65 year historical review of the study of consumer psychology begins in the last decade of the 19th century. The study of consumer psychology emerged from specific interest in advertising and how advertising influenced people. By the latter half of the 19th century, the advertising industry was well established in the United States. Its growth as an industry paralleled the industrial growth of this country. In the United States the first organized advertising appeared in colonial times and was enhanced through the advent of urban newspapers. As the country expanded, there was an obvious need to extend the reach of advertising. From 1850 to 1900, transportation and technology brought on a “new industrial age.” An explosion in manufacturing productivity led to new factories, increased volume, greater diversity in consumer products, and the need for new markets (Oliver, 1956). Advertising became the critical vehicle for achieving growth. As new markets emerged reflecting new populations centers, so did the concept and practice of national advertising with the advent of large circulation magazines like *Atlantic Monthly*, *Colliers*, *Cosmopolitan*, *Harper’s Monthly*, *Ladies Home Journal*, *McClure’s*, and the *Saturday Evening Post* (Kuna, 1976).

The second half of the 1800s witnessed the advent and growth the advertising agent, the advertising copywriter, and, subsequently, the advertising agency. A new found need for professionalism resulted in numerous ad clubs, associations, trade journals, and codes of ethics (Wiebe, 1967). During this time period, two schools of advertising emerged (reflecting, but not to be confused with the dominant theoretical perspectives in economics and psychology). The first school was based on a rational view of man, the potential consumer who carefully paid attention to promotional messages before making product choices. The purpose of advertising was simply to inform the public that the item was available and what it could be used for. The public was viewed as skeptical and mostly incapable of being persuaded to act against their better judgment. This rational perspective

followed classic economic theory that people are self-interested and naturally desire to maximize profits while valuing their time. Not surprisingly, the emphasis was therefore on reasonable price and basic selling points.

While the rational school was dominant during the 1890s and early 1900s, by 1910 it was supplanted by the non-rational perspective. Followers deemed it likely that the emotions of the public could be manipulated and that people could actually be persuaded to purchase goods. This school was much more open and receptive to a psychological approach to understanding audience response to advertising. Also contributing to the non-rational school was psychology's new emphasis on the unconscious and motivational states (e.g. Freud, 1924/1969), as well as on the mechanistic reinforcement of behavior (e.g., Watson, 1913).

EARLY ROOTS TO THE STUDY OF CONSUMER PSYCHOLOGY

As is the case with most all of experimental psychology, one must go back to Germany in the latter part of the 19th century to understand the roots of what was ultimately to become consumer psychology. These roots began in the laboratory of Wilhelm Wundt (1832–1920) in Leipzig in 1879. Of particular relevance to the study of consumer psychology was Wundt's focus on the topic of *attention* and his influence on a subset of students who would go on to become, much to Wundt's displeasure, the first applied, industrial/organizational psychologists in America. Wundt (as did James and Titchener) believed that psychology needed to first prove its worth and evolve as a pure science before it could adequately respond to problems of the applied world (Kuna, 1976).

During this same period of time, William James (1842–1910), trained as a philosopher, was bringing to light the new science of psychology in his laboratory at Harvard University. James promoted a mentalistic perspective for this new science. In his seminal book entitled *The Principles of Psychology*, he defined psychology as the “science of mental life, both of its phenomena and their conditions” and, like Wundt, professed that this young science needed to rely on introspective observation (James, 1890/1950).

The focus on this mentalistic approach to attention continued with Wundt's students, Edward Bradford Titchener (1867–1927) at Cornell and Hugo Munsterberg (1863–1916) at Harvard. While Titchener felt applied psychology was premature at best, Munsterberg became the first important voice in the promotion of applied psychology. Indeed, in the 1909 edition of *Psychological Bulletin*, he promoted founding of the department of applied psychology as part of the Harvard Psychological Laboratory (Munsterberg, 1909). In this announcement he calls for research on “psychotechnical studies, dealing with the psychological conditions in our technical civilization in business and commerce and industry...” (p. 49). He arguably was the first true industrial/organizational psychologist. Although he did little himself to contribute to knowledge regarding consumer related psychological topics, his promotion of applied psychology in business settings, in the face of the purists, provided significant professional support for those psychologists scientifically investigating applied business topics. Other students of Wundt's who reinforced the mentalistic focus but turned their interests toward the study of advertising, included Edward Wheeler Scripture at Yale, Harlow Gale at the University of Minnesota, and Walter Dill Scott at Northwestern University.

The most dominant belief of the mentalists was ideo-motor action. James (1890/1950) defined it this way:

That every representation of a movement awakens in some degree the actual movement which is its object; and awakens it in a maximal degree whenever it is not kept from so doing by an antagonistic representation present simultaneously to the mind. (p. 526)

James viewed ideo-motor action as immediate, that the representations of the movement in the mind remain for a matter of seconds (or less) (James 1890/1950).

In the early part of the new century, the mentalistic approach had two challenges: behaviorism and dynamic psychology. The two pioneering advocates for behaviorism in America were Edward Lee Thorndike (1874–1949) and John Broadus Watson (1878–1958). Each attempted to discredit the mentalistic approach (as well as the functional approach) by advocating a mechanistic view of behavior.

Dynamic psychology, reflecting the dynamic (changing) nature of human behavior, prescribed that man was better understood through instinctive, unconscious, biologically driven actions (Watson and Evans, 1981). The two leading proponents were Sigmund Freud (1856–1939) and William McDougall (1881–1938). Freud was first formally introduced to American psychology in 1909 during his famous visit to Clark University at the invitation of G. Stanley Hall. Because behavior was in constant flux, dynamic psychologists viewed the conscious state as less important and less reliable than the unconscious state. McDougall (1912) was the first to propose that rather than being a study of consciousness, psychology was more accurately the study of behavior. He focused on the notion of innate instincts that drive men (and animals) towards goals. Both Freud and McDougall believed that tension reduction was at the root of all motivation and behavior. Their perspectives were reflected in the non-rational school of advertising emerging at the same time (Kuna, 1976). Their theories were obviously antithetical to both the mentalistic and the mechanistic perspectives. This established interesting conflicts and debates, both among “pure” psychologists as well as those psychologists seeking to focus on applied settings.

THE EARLY PIONEERS: 1895–1930

E. W. Scripture and Harlow Gale

Although Edward Wheeler Scripture (1864–1943) and Harlow Gale (1862–1945) are not considered by some to be true forefathers of consumer psychology (see Benjamin, 2004), they appear to be the first psychologists interested in consumer related issues, and specifically consumer response to advertising (Scripture, 1895; Gale, 1900). As such, their work is part of the history of consumer psychology. In perhaps the first discussion of psychology as it pertains to advertising, Scripture (1895), implicitly employing Wundt’s notion of involuntary attention, denoted several psychological “laws” as they relate to advertising. For example, Scripture noted that “bigness” and the intensity of a sensation regulate attention to commercial promotion, noting the effectiveness of signage and lighting in stores and theaters. Scripture also considered feeling and expectations, proposing that “the degree of attention paid to an object depends on the intensity of the feeling aroused,” and that the level of our expectations would determine the amount of attention paid to an object (Kuna 1976). Here Scripture hints at the notion of incongruity as attracting attention (e.g., putting notices upside down). Although Scripture discussed these psychological issues related to advertising and business, he left it up to others to do the scientific investigation.

Harlow Gale, an instructor at the University of Minnesota, picked up Scripture’s call for greater scientific investigation. Gale (1900) conducted what many argue to be the first actual scientific studies of advertising and consumer behavior. He began with a qualitative survey mailed to advertising professionals where he posed a series of open-ended questions designed to provide practitioner opinions about the best means to attract attention and induce purchasing through advertising. The survey required significant effort and resulted in only a 10% response return. Gale then followed the survey with a series of experiments, employing the tachistoscope procedure learned from

Wundt. The attentional issues he examined included relevant versus irrelevant materials (words and advertising “cuts” or representative images), large versus small style of type, the side of the page first attended to, exposure levels, and colors used in advertising. As he moved from one study to another, he discovered potential confounds and attempted to correct for them in subsequent studies. Perhaps of interest at the time, but not surprising today, he found that gender moderated some of his effects.

It is interesting to note that Gale may have been the first to use the order-of-merit technique in determining the importance of message arguments. Gale would ask respondents to rank order brands based upon the information provided in advertisements. E. K. Strong Jr. (Strong will be discussed in depth in a subsequent section) first attributed this technique to James McKeen Cattell (Strong, 1911), but later reversed himself, giving credit for the method to Gale (Strong, 1938; see also Kuna, 1979). This method was widely used by subsequent researchers in advertising and business studies (but challenged by Adams, 1915, see further discussion later in this chapter). Gale confined his work to conducting studies within his classroom and was not willing to establish relationships with members of the advertising industry. He was more interested in giving his students practical experience with psychology.

Walter Dill Scott

At the turn of the century, the emphasis in psychology was transitioning from a mentalistic perspective, an ideational-cognitive explanation for unconscious phenomena, to the more dynamic notions of instinct and emotion. No more is this transition evidenced than in the long career of Walter Dill Scott (1869–1955). Scott is considered by many as America’s first business psychologist and the first true applied psychologist (Jacobson, 1951). Unlike Gale, Scott actively promoted his findings to business and often served as a consultant. After his educational studies with both Wundt and Titchener, he began his academic career as a professor at Northwestern University, eventually serving as its president. Aside from studying advertising, he also published in the areas of salesmanship and classification of military personnel.

Scott was the first to actively promote the psychological study of advertising. He was very vocal in a series of 12 columns that appeared in *Mahin’s Magazine* and challenged the thinking of those who rejected a scientific approach, then represented in *Printer’s Ink* (Kuna, 1976, Watson and Evans, 1981). His first book, *The Theory of Advertising* (1903), was a compilation of those articles, and was written from a mentalist perspective, purporting that creating involuntary attention was the motive for advertising. This book, like his second, was filled mostly with advice for practitioners, although it did cite a few select studies. Like Scripture, Scott listed a number of “laws” and principles. These reflected numerous psychological dimensions and elements inherent in advertising as described in his chapters: apperception/attention, counter influences on attention, intensity of sensation, context effects, comprehension, repetition and rehearsal, mental imagery, laws of association, suggestion, perceptual illusions, and intensity of feeling (Scott, 1903). By 1905 Scott was deep into solving applied problems for business through various research methods. He was also authoring articles for other magazines including the *Atlantic Monthly*, *Business World*, and *Advertising World* (Kuna, 1976).

John Mahin asked Scott for more articles and Scott obliged with 21 more columns. This second set of articles formed his second and most famous book. *The Psychology of Advertising* (1908), while still maintaining a mentalist perspective, combined new irrational aspects of consumer behavior to include emotion and instinct, with the old focus on attention and suggestion. More studies were included that incorporated new methods: naturalistic observation, longitudinal study, order-of-

merit, and memory value of advertising. His thoughts on suggestion in basic psychology became invited articles in the *Psychological Bulletin* (1910–1916). Scott believed that humans were susceptible to suggestion and that the force of suggestion could lead to action. Effective advertising, according to Scott, should suggest a course of action in a manner that ruled out other contrary actions.

There are many examples of Scott's influence on advertising practitioners including his advice on the association of the advertising with the product (laws included repetition, recency, and vividness), direct commands embedded in advertising, and suggestion as how advertising works with couponing (Scott, 1916). He provided testimony from companies as to the success of his propositions. Of special note is the fact that Scott never published his studies in academic journals nor presented this work at academic conferences, even though he served as APA president.

Daniel Starch

One could say that Daniel Starch (1883–1979) followed in the footsteps of Walter Dill Scott, carrying on the mentalist tradition. Like Scott, Starch's applied research never appeared in an academic journal. During his time in academia, he chose to reinforce his reputation as an experimental psychologist, publishing on traditional topics including a series of review articles for *Psychological Bulletin* (1911–1916) on the topic of auditory space.

Yet Starch differed from Scott in that he attempted to bring an objective scientific view to all of his work. Rather than offering subjective opinions about the psychology of advertising, all of his contentions appear to be empirically supported. Starch reinforced the mentalist approach in his focus on attention, suggestion, and instinct, but he extended it by introducing the concept of consumer "interest," which he later labeled "appeals" (e.g., Starch, 1923).

Starch spent most of his relatively short academic life at the University of Wisconsin (1908–1919) and at Harvard (1920–1926). His first book titled *Principles of Advertising* (1910) consisted of two parts: attracting attention and securing action. While primarily focusing on the attention oriented topics of Scott, Starch did add the notion of primacy and recency of advertisements as attracting more attention in the mind of the consumer. While both Scott and Hollingworth mentioned the importance of optimal length of line in print advertising (as noted in Tinker & Paterson, 1928), Starch was the first to actually conduct studies on this important question (Starch, 1924, 1923).

Starch's second book was published in 1914. This book addressed not only the psychology of advertising, but also other non-psychological topics like advertising strategy and ethics. The book was again organized around attention and securing response. Several laws of attention were presented to include the laws of intensity, counter-attraction, and contrast. In securing a response, Starch focused on argumentation and suggestion. It was under the latter that Starch introduced the strategy of stimulating consumer interest. Interest was an extension of attention, a kind of involuntary prolonged attention to an object. It was assumed that a reader of an ad would be more likely to attend and respond if the stimuli presented in it reflected the reader's interests. He suggested that illustrations could be used to stimulate interests. This book became a standard for the advertising practitioner. It is important to note that for every topic, Starch went to significant lengths to support his contentions with empirical evidence from his own studies or the work of other psychologists or practitioners.

In 1924 while still at Harvard, Starch became heavily involved in supervising research for the American Association of Advertising Agencies. In 1932 Starch left academia altogether and started Daniel Starch & Staff, a marketing research company providing subscribing companies with data on the effectiveness of their ads. Starch became well known for his methodological innovations, including the Starch Recognition Procedure in 1922, which measured consumer reading habits,

and the Buyometer in 1948, which isolated the influence of magazine advertising on sales (Kuna, 1976). He retired in 1968 at the age of 85.

BEHAVIORISM IN ADVERTISING RESEARCH

While the mentalistic approach was prevalent at the turn of the century, it was not without challenges. One of those challenges came from the faculty at Columbia University. James McKeen Cattell (1860–1944) had established multiple university laboratories for the study of psychology after returning from the tutelage of Wundt in Leipzig. He welcomed new faculty and students to Columbia in the early 1900s, especially those who had interests in applied psychology. Indeed, over time he recruited a remarkable group of faculty to include Robert Sessions Woodworth (1869–1962), Edward Lee Thorndike (1874–1949), Harry Levi Hollingworth (1880–1956), Edward Kellogg Strong Jr. (1884–1963), and Albert T. Poffenberger (1885–1977).

Thorndike (1911) had introduced laws of effect (i.e., the role of “satisfiers” and “annoyers” as reinforcing and inhibiting behavior) and exercise (i.e., connection of a response to a situation). In applying these laws to advertising, Hollingworth felt that, rather than focusing on whether an ad attracted someone’s attention, the true measure of the effectiveness of an ad is ultimately reflected with the actual purchase behavior. Hollingworth held that research conducted by advertisers was by its very nature, flawed, as it didn’t control for numerous extraneous variables (seasonal sales, competitor actions, amount of media, etc.). Hollingworth had advertisers send him ads to test in his lab. Interestingly, his lab tests were highly correlated with the actual sales figures related to each ad.

In several studies, Hollingworth (e.g., 1911) examined the same variables considered by Gale and Scott, (e.g., images, wording, size, color, position, and type style) but considered the variance of the response rather than introspection. As his studies progressed, he considered individual differences such as gender and socioeconomic differences. In some cases his results contradicted the results of Gale and Scott. Hollingworth even constructed a panel of New York City residents, the first systematic effort to track consumption behavior (Kuna, 1976). In 1913, *Advertising and Selling: Principles of Appeal and Responses* was published. Building on his earlier work but appearing to move away from behaviorism, his next book on the topic, *Advertising: Its Principles and Practice* (1915) captured four principle functions of advertising: securing attention, holding attention, establishing associations, and influencing conduct by making associations dynamic. Hollingworth’s objectivity in his empirical methods clearly influenced other younger applied psychologists. One of these was Edward K. Strong Jr.

Thorndike’s (1913) classic paper rejected ideomotor action and promoted new laws of habit, effect, and exercise, Watson released his treatise on behaviorism (1913), and Hollingworth’s (1913) book reflected aspects of this new wave of thought. Cattell had earlier challenged the claim that introspection was the most valid methodology for the study of psychology. His focus was on reducing qualitative responses into quantitative data. As an example, his version of the order-of-merit method was strictly objective, requiring subjects to order stimuli on some criterion (Kuna, 1976; 1979).

Strong and Hollingworth took a more “molar” view of behaviorism, with a focus on complex stimuli as opposed to discrete stimuli. Rather than being preoccupied with people’s thoughts, they measured what they felt were surrogates for behavioral response to advertising stimuli. They employed the order-of-merit method as well as a refined recognition test that Strong (1914) developed in a reaction to the traditional mentalist recall measures. Strong believed that recognition was the best surrogate for actual purchase behavior and tested the influence of several presentation variables to include size and frequency, and repetition intervals (e.g., Strong, 1912, 1913, 1914).

One other behaviorist from this time period is worth considerable note. It is important to reflect on the contribution to consumer psychology of John Broadus Watson. His treatise on behaviorism in 1913 earned him great acclaim as a psychologist, as he informed the world that efforts based on psychology principles should lead to greater control and prediction of behavior. Watson's studies provided demonstrations of the influence of association and conditioning on behavioral responses (e.g., Watson and Raynor, 1920). He loudly and passionately disclaimed any reason for a mentalist perspective. He became the chair of the psychology department at Johns Hopkins University, editor of the *Psychological Review*, and served as a president of the American Psychological Association in 1915. However, a scandal led to his termination and exit from academic life, and a transition into a career in advertising. Stanley Resor, the "dean of American advertising," hired Watson to work for him at J. Walter Thompson in New York. Watson quickly found leverage for success in his psychological expertise. The business world embraced him and his leadership and philosophy resulted in numerous successful advertising campaigns. Resor showcased Watson in such a way that it legitimized the role of psychologists working in advertising.

ADVANCING AND APPLYING THE PSYCHOLOGICAL SCHOOLS OF THOUGHT

To understand how dynamicism eventually evolved from mentalistic and behavioralistic approaches, one needs to consider the influence that Freud had at the time. His influence was subtle. Although Gale, Scott, and Starch all brought forth such notions of the unconscious as instincts, emotions, and interests, they continued to offer explanations consistent with a mentalistic outlook. Thorndike (1911) explained instinct and motivation as an inherited response tendency, adhering to a behavioral explanation where the catalyst for the response was a stimulus, not a condition of the being. It was McDougall who took direct aim in differentiating his purposive psychology from Watsonian behavioral psychology as reflected in the following passage:

The two principal alternative routes are (1) that of mechanistic science, which interprets all its processes as mechanical sequences of cause and effect, and (2) that of the sciences of mind, for which purposive striving is a fundamental category, which regard the process of purposive striving as radically different from mechanical sequence. (1923, p. vii)

Enter Robert S. Woodworth, a colleague of Thorndike and Hollingworth at Columbia. Woodworth is credited with putting the organism in the stimulus-organism-response (S-O-R) model and thus finding a home for the contribution of motivation and instinct to human behavior. In his book *Dynamic Psychology* (1918), he attempted to bring together (and even expand) the work of Freud and McDougall with mainstream psychology. It is important to note that the term "psychodynamic" as often describes Freud and his adherents' theories, is not viewed as the same as "dynamic psychology." While both referred to notions of the unconscious mind, the former term typically includes identification of certain emotional conflicts and the resolution of these conflicts with specific defense mechanisms. Dynamic psychology was focused upon the influence of basic motivational drives on behavior. McDougall spoke of "drives" as strong and persistent stimulation, as initiating goal-directed actions through selective excitation of response mechanisms related to particular goals (e.g., consumption behaviors). Hollingworth and Strong, as colleagues of Woodworth, were naturally exposed to his thinking and his ideas regarding drives and organism responses, even his early ideas on psychoanalysis. Indeed, Hollingworth earlier had occasion to meet Jung and be exposed to Freud's ideas.

Although Hollingworth and Strong were reticent to adopt the dynamic approach, Hollingworth challenged business leaders to better understand the role of motives, interests, and instincts (Kuna,

1976). Finally, in Hollingworth's multiple-authored book, *Advertising: Its Principles and Practice* (Tipper, Hollingworth, Hotchkiss, & Parsons, 1915), he provided a listing of a hierarchy of human needs (e.g., comfort, play, sociability, competition, shyness, revenge, and pride) as representative of the individual, not a specific stimulus. He also revised his functions of advertising from his previous book to now include tabulation of the fundamental needs of men and women, analysis of the satisfying power of the commodity in terms of the consumer's needs, establishing the association between need and commodity, and making the association dynamic. This was a remarkable transference. Strong too experienced this transference and by 1925 his thinking culminated in his book, *The Psychology of Selling and Advertising*.

While Strong provided leadership in the adoption of the dynamic approach to applied psychology, his eventual fame came from a different applied focus. Although he continued to conduct research in advertising, he also served on the committee on Classification of Personnel during World War I. In 1923, he published the Strong Vocational Interest Blank (SVIB) which became the most widely used career interest inventory in publication, a revision of which is still employed today in helping individuals understand their natural work propensities.

The influence of the work of Hollingworth and Strong on other psychologists was considerable. Another Columbia colleague, Joseph V. Breitwieser, made extensive reference to the work of both Hollingworth and Strong in his textbook *Psychological Advertising* (1915). Their work to adopt the order-of-merit method resulted in subsequent usage by many investigators. By 1923, Starch had conducted at least 34 studies using the method.

Henry Foster Adams and Dexter Kitson

In his book entitled *Advertising and Its Mental Laws* (1916a), Adams appears to be carrying on the mentalist tradition by specifically citing the work of those we've previously discussed: Gale, Scott, Hollingworth, Strong, and Starch. However, Adams himself conducted numerous empirical studies. Adams believed in testing factors in isolation applying a "mathematical exactness" in examining various elements found in advertising. Although he respected their contributions, Adams was especially critical of Hollingworth and Strong's use of the order-of-merit method (Adams, 1915). In *Advertising and Mental Laws* he repeats his criticism but also devotes one chapter on the use of statistical tools to examine response to advertising (correlation and variance), and another on experimentation in advertising.

One important contribution from Adams' book was his ordering of certain advertising stimulus factors, as he perceived them related to key response variables: attention, association, memory, perception, and aesthetics. Adams also considered the effectiveness of different media. He concluded the book with chapters on fusion (a nod to behaviorism) and action. The book, for the most part, was still a tribute to the mentalistic approach. His concluding chapter dealt with the empirical findings related to gender differences. He noted that women paid attention more to size, personal appeals and observed events while men attended more to successive presentations, pictures, industrial-job related, and recommendations of authorities. Of peculiar interest, he found that memory tests contradicted the attention effects. For example, women had better memory with successive presentations and pictures, while men had better memory based on size of ad and for trade names.

The comprehensive books by Adams and Starch, each promoting the importance of the empirical results to date, set the tone for much work to follow. In a short period of time following these books, numerous studies were reported. For example, Adams (1916b), still maintaining the mentalist approach, went on to study the relative memory for duplication and variation, and sizes of ads (Adams 1917), as well as the effect of order of presentation (Adams, 1920).

Henry Dexter Kitson helped set the stage for this focus on other aspects of the consumer in his book titled *The Mind of the Buyer*, published in 1921. His first chapter examines the “stream of thought” in a sale, prescribing six stages in a sale: attention, interest, desire, confidence, decision and action, and satisfaction. The book clearly takes an eclectic approach, citing researchers and theorists from all three schools of psychology: mentalist, behaviorist, and dynamic. Kitson contributed to the study of advertising as well, especially with his studies regarding illustrations within advertising (Kitson, 1921), and more specifically the use of color (Kitson, 1922a), various art forms (Kitson, 1922b), package illustrations (Kitson & Campbell, 1924), and illustrations containing people (Kitson & Allen, 1925). Indeed, in 1921, Kitson presented his “historical method of investigating problems in advertising.” This appears to be the first documented use of content analysis methodology in advertising studies. In 1925, Kitson and Allen reported a trend in the usage of illustrations containing people in advertising, after analyzing 20 years of ads from *Saturday Evening Post*, *Literary Digest*, and *Women’s Home Companion*. This continued focus on illustration is one of the first examples of programmatic research in consumer psychology.

Albert T. Poffenberger

Albert T. Poffenberger (1885–1977) studied at Columbia under Cattell and Woodworth. The influence of these associations are reflected in his lifelong interest in physiological psychology and objective response. His dissertation was titled *Reaction Time to Retinal Stimulation* (Wenzel, 1979). He never lost this interest and continued in this vane through much of his career. However, his strongest interest was in the area of applied psychology (see 1921 edition of *American Men in Science*). After conducting a number of studies, he published the book entitled *Psychology in Advertising* in 1925. This imposing tome is a remarkable recapitulation of all the conceptual and empirical work up to that time. Aside from a thorough review of traditional subjects like memory and attention, and some focus on methodology, statistics, measurement, and appeal, Poffenberger provided new reviews in comprehension, “feeling tone,” attitude, human desires, and individual and group differences, among others. Poffenberger followed this book with *Applied Psychology: Its Principles and Methods* (1927, 1932). Here he defined applied psychology as “every situation in which human behavior is involved and where economy of human energy is of practical importance.” In the section on Advertising and Selling, he explores the desires, habits, and logic of the consumer, and reviews the state of psychology as it has been applied to advertising and selling strategies to date. Poffenberger contributed heavily to the service of the discipline culminating in his election to the presidency of the APA in 1934.

OTHER CONTRIBUTORS DURING THIS TIME PERIOD

Others, notably Heller and Brown (1916) in their study on memory for street-car signage, Laslett (1918) in a study of relevance of illustrations, Hotchkiss and Franken (1920) in their study of attention factors, and Turner (1922) in his examination of testimonials used in advertising, continued the mentalist tradition. However, a number of applied researchers were beginning to employ more objective measures reflecting a clear leaning toward the behavioral approach. Poffenberger was arguably the most prolific examining face types (Poffenberger & Franken, 1923), return of coupon resulting from advertising (Poffenberger, 1923a), belief consistency with advertisement (1923b) and the value of lines used in advertising (Poffenberger & Barrows, 1924).

In what was to become a significant subject of study, as we shall see in the next section of this chapter, Nixon (1924, 1926) examined attention and interest in advertising and concluded that dif-

ferences in attention between color ads and black and white ads lasted only briefly. He voiced concern over the reliability of differences in memory tests between the two types of ads, and designed and employed a method whereby researchers could observe where visual attention was focused. Up to this point, researchers from Gale forward suggested that more attention would be paid to relevant messages about products as opposed to irrelevant messages. Likewise Laslett (1918) found that relevant illustrations led to better recall. However, using Nixon's method of "visual fixation," irrelevant pictures paired with products garnered more attention than did relevant pictures.

As was noted above (and will be discussed in depth below), at this time psychologists began to consider other aspects of consumer behavior. For example, Geissler (1917) pointed out that consumers needed to be approached in more ways than just advertising and began to study processing that occurred in consideration of purchase. Heller (1919) studied the impact of package labels on purchasing, while Kitson (1923) authored a conceptual article examining the consumer's role in market strategy. Laird (1923) compared demographic and socioeconomic differences in the selection of toothpaste, and Hotchkiss and Franken (1923) considered the importance of brand familiarity.

James McKeen Cattell was eventually dismissed from Columbia because of his opposition to the draft. In 1921 he, along with Columbia colleagues Woodworth and Thorndike, formed the The Psychological Corporation in New York. They began by developing psychological tests and related materials that could be used in education, business, and government. In the following years, the company hired academics to run sponsored studies. As we shall see, a number of these research studies were eventually published in academic journals. It is interesting to note that through mergers and acquisitions, the corporate entity evolved and still exists today although under a different name (Harcourt Assessment).

THE POST-DEPRESSION ERA THROUGH WORLD WAR II: 1935–1945

The end of the Depression triggered significant research by economists studying product demand and usage. The *Journal of Marketing*, initiated in 1935, devoted a significant amount of journal space to articles authored by individuals trained in economics and measuring product demand and use. During this same period, applied psychologists were attempting to better understand consumer response to commercial product promotion. The decade following the depression was marked by the advent of a new media form—radio—that quickly found significant application for commercial advertising. As we shall address next in this section, there were numerous areas of consumer research that appeared to be focused on print and radio effectiveness (including comparative effectiveness); salesperson effectiveness; consumer preference, consumer motivation, and concern over research methods. We shall take each in turn and discuss how these applied psychologists addressed these various consumer related interests and issues. It is interesting to note that unlike the prolific work from key pioneers during the previous time period, this time period is marked with contributions from authors who published but a few articles reflecting consumer psychological topics. However, this work, in bulk, does demonstrate a significant level of progression forward in the discipline.

FOCUS ON MEDIA DIFFERENCES

Several applied psychologists approached the issue of comparing the effectiveness of visual versus spoken ads by mimicking the differences between print, posters, and radio media. This effort was initially reflected in a significant number of memory studies. Burt and Dobell (1925) reported a

series of studies that sought to replicate Ebbinghaus' (1885) notion of a forgetting curve, one that begins with a sharp decline flattening out over time. These researchers provided respondents with a long paired list of products and fictional brand names, two studies projected onto a screen, (over different time frames) and one provided by audio means. The results of all three studies reinforced the same type of forgetting curve, but the initial audio memory test yielded better results in both recall and recognition than did the projected pairs on a screen.

Noting that advertising posters seen on streets are also an important type of advertising, Brutt and Crockett (1928) studied memory for different types of posters. Their results reflected significant primacy and recency effects and that distance from the viewer makes a difference in memory for the add (reflecting the best visual angle). Stanton (1934) and Dewick (1935) conducted similar experiments where they provided a series of print advertisements and spoken advertisements in a counterbalanced study using common products. The brand names were mentioned three times in the script which lasted about 35 seconds. They then recorded recall scores for the product class and the brand name, employing both immediate and delayed recall tests. The findings of both studies revealed that there were no consistent differences upon immediate recall. After 5 to 7 days, there was the beginning of a favored auditory response, and in the Stanton study significant differences favoring auditory response were found for 21-day recall. In the Dewick study, recall of "ideas" mentioned in the advertisements were elicited, and while both visual and auditory memory decayed after 6 days, the visual decay in memory was significantly greater than the auditory. In hindsight, it would be interesting to know, in the delayed conditions, if individuals during their everyday normal experience, heard or read more ads for the products used in the study. If the former, that might explain the greater recall scores for auditory messages due to greater exposure to the brand name, product class, and advertising message. It is interesting to note that in the early 1930s William Stanton, while a PhD student at Ohio State, developed a forerunner of the radio and television rating audimeters, later developed for A.C. Nielsen by MIT. Stanton went on to become an executive with Columbia Broadcasting Company and an important pioneer in subsequent radio audience studies (Maloney, 1987, as cited in Kassarian, 1994).

In perhaps what was a precursor to television and was reflected in the speaking movies of the time, Elliot (1936, 1937a, 1937b, 1937c) reviewed the literature on memory of visual and auditory stimuli dating back to Ebbinghaus and developed a series of studies comparing visual, auditory, and the combination of visual and auditory (termed "television" in one of his studies). In all cases, he found an advantage for the combination of the two as regards memory for an advertising message as well as a trade name. His studies also revealed certain gender effects but these effects were somewhat inconsistent across studies. In general, the difference of effectiveness of television over other modes was stronger for women than men.

A number of studies attempted to understand people's attitudes toward radio advertising in general (Cantril & Allport, 1935; Kornhauser & Lazarsfeld 1937; Sayre, 1939). Cantril and Allport, and Kornhauser and Lazarsfeld employed two measures (estimated time that commercials were heard, and amount of money willing to pay annually to remove advertisements) that they deemed reflective of possible positive or negative attitudes towards radio advertising. However, employing a Likert scale, Sayre found no correlation between a direct measure of attitude and the other two scales.

William Stanton, mentioned above, conducted radio studies under the guidance of Cantril and Allport at Princeton. The three were instrumental in bringing Paul Lazarsfeld to the United States. Lazarsfeld, a mathematics PhD from the University of Vienna, had established a radio research organization in Europe and conducted the first major study on radio audience listening. Lazarsfeld soon left Princeton and founded what was to become the Bureau of Applied Social Research at Columbia University. Lazarsfeld, in turn, was instrumental in bringing his Viennese students,

Ernest Dichter and Herta Herzog to the U.S. Dichter's contribution to consumer psychology will be discussed in a subsequent section (Maloney, 1987 as cited by Kassarian, 1994).

Guest and Brown (1939) tested recall for radio advertising based on a number of variable differences. In a controlled study employing both ads and music programming for an hour, they found no differences for temporal position, whole versus part methods of presentation, nor for repetition. They did find an inverse relationship between recall and amount of material, less material presented led to better recall. In all cases, the average number of thought passages retained was small. Wolfe (1941) found a high correlation, .78, between women who could associate a product with a program. These strong results for early radio recall are intuitive given that each program was typically sponsored by only one product. Thus the repetition of the program with one sponsor likely led to a high level of rehearsal and retention. Fay and Middleton (1941) examined the gender of commercial announcers and found no differences in gender preference for announcers, but found that women tended to have a higher preference for announcers across both male and female products, then did males.

FOCUS ON MECHANICAL FEATURES OF PRINT AND POSTER ADVERTISEMENTS

Several important mechanical factors in print advertising were considered during this time period as they influenced reader response. The impact of color in advertising took center stage in the early 1930s along with an examination of positioning, type style, and amount of copy.

In the latter half of the 1920s and early 1930s, several studies pertaining to color, size and position in print advertising appeared. Nixon (1926, 1927) reported the first of several perceptual studies. These two studies compared color and black and white ads, using a measure of attention to the ad. He found no significant differences between color and black and white ads but did find that females tended to pay more attention to the ads than did males. Sumner (1932) studied the influence of color on legibility (blue print on a gray or white background scored highest however there were only 5 subjects. Dorcus (1932) examined people's habitual word associations with colors as they might be a factor in advertising (for a comprehensive review of studies on response to color going back 30 years, see Dorcus 1926). As noted in a 1932 edition of *Printer's Ink*, Starch, in an analysis of 5 million inquiries, studied 4 million returns from 3,349 advertisements. He found that "color ads brought 53% more returns per 100,000 than did black and white advertisements of similar size and character" (p. 65).

While still considering the effects of color, researchers also began to consider size and placement issues. In 1930, Cutler reported no recall differences for the same ad that appeared in magazines of different size. Ferguson (1934) supported Starch's findings by comparing position of magazine advertisements in the *Saturday Evening Post* (e.g., inside front cover, page opposite the table of contents, outside back cover), and found some differences for position, but also found that color typically out-performed black and white ads. Ferguson made an additional interesting contribution by noting potential differences in target readership: "those who buy *SEP* in order to read the articles and stories, 2) those who buy *SEP* for humor, and 3) those who buy *SEP* to mainly look at the ads." Ferguson (1934, 1935) concluded that contrary to belief, his findings revealed no relationship between the size of an advertisement and its attention value, no preferred positions, and no preference for right versus left hand pages, nor position on the page. Lucas (1937) employed a more sophisticated study as a follow up to Ferguson and found contradictory results. Specifically he found that the differential changes for the advertising by placement and size correlated strongly with recall and recognition, that women respond better to color than men, and that right- and left-hand page locations are of equal value for full-page ads, but right-hand position is better recalled

for smaller ads. Guilford and Ewart (1940) examined the difference in reaction time resulting from the potential distraction of print ads that appeared in color or black and white. Listening and responding to the noise of the timer motor which was about the same decibel as the projector of the ads, they found that both types of ads served as significant distractors, but did not differ in reaction time. McNamara (1941) voiced the criticisms regarding previous attention and memory studies in the lab (see subsection on methodology below for these criticisms), and reported a study employing eye movement photography. He found no differences in attention to the prime positions (inside front, back, etc.), nor for right- versus left-hand pages, but did find differences favoring two-column ads found on the outside left page and ads that were found in the upper corners.

The continued investigation into typeface response was another mechanical feature of the early 1930's. In 1933, Davis and Smith, building on the earlier work of Poffenberger and Barrows (1924), considered emotional response to different forms of typeface. Respondents were asked to match typefaces with advertised products as well as emotions, revealing some differences based on such typeface characteristics as size, condensation, boldness, use of italics, etc. In a similar study, Schiller (1935) replicated the earlier study of Poffenberger and Franken (1923) examining the effectiveness of certain types of typefaces as representing certain products. However, in her study she also considered color of the typefaces.

In a follow up to Kitson's earlier content analysis on the use of illustrations, Klapp (1941) found that not only did advertisements without pictures decrease significantly over 4 decades (1900–1940), as did ads with pictures but not including people, but that ads with people, especially reflecting relevancy with the product, increased dramatically (1900—16.2%; 1915—34.7%; 1930—49%; 1940—67.1%).

One popular question of advertising effectiveness that still evokes research today is the issue of relative effectiveness of negative versus positive message appeals. Investigation of this question can be traced back to the historical content analysis work of Harry Kitson (reported in Lucas & Benson, 1929a). Kitson's conclusion as well as Scott's was that in general, it was best to use positive appeals. Kitson based his opinion on the usage rate differences found in his content analysis favoring positive appeals. However, it is interesting to note that some practitioners of the day disagreed (Lucas & Benson, 1929b). Lucas and Benson undertook a program of research on this topic with a series of experiments. Reinforcing the practitioner opinion, across varied message appeals (negative versus positive) reflecting ads for several different product classes, these researchers found no differences in the amount of coupons returned based on the valance of appeal type (Lucas & Benson, 1929b), and no differences in recall among adults (Lucas & Benson, 1930a). However, they did find that among children, positive ads were recalled better than negative ads, especially among boys. They noted that as children age, differences between appeals and gender disappear. Lucas and Benson (1930b) also published *Psychology for Advertisers*, an extensive book that summarized advertising effectiveness research to date, and focused on the mechanics of print appeals and how these appeals could facilitate the effort of salespeople.

Focus on the amount and proximity of ads: In 1935, Fred McKinney designed a study to examine "retroactive inhibition." In earlier basic psychology studies, numerous results reflected "retroactive inhibition, distraction due to similar material that appears immediately subsequent to the targeted stimulus presentation. In his first study to apply retroactive inhibition to advertising, McKinney sought to discern how memory for parts of an ad (i.e., product name, slogan, headline, reading and picture content), are susceptible to subsequent reviewing of ads. McKinney found slight retroactive inhibition with slogans being the most affected and name of product the least affected. He does draw the obvious conclusion that placement of ads in relative isolation is the most

effective for memory of the ad. Blankenship and Whitely (1941) focused on the effects of proactive inhibition to memory by providing both normal and similar preceding stimulus ads (containing a list of products and associated prices and comparing them to conditions containing a similar list of nonsense names and associated numbers. After subjects were asked to recall the inhibitory stimulus lists, they were then exposed to a regular ad with listed products and associated prices, and recall scores were taken. The results consistently demonstrated a proactive inhibition effect on memory. In a similar application, McNamara and Tiffen (1941), using the Purdue Eye Camera, found that ads adjacent to cartoons inhibited the time spent on the advertising.

Franzen (1940), in perhaps the first look at fatigue resulting from clutter, examined ad visibility reported in interviews comparing two magazines, one with 33% more advertising than the other. More fatigue was clearly present in the interview assessing memory for ads in the larger magazine.

FOCUS ON THE EFFECTIVENESS OF SALESPEOPLE

Salesperson effectiveness was viewed strictly as a “personnel” issue in the early part of the 20th century. Many applied psychologists developed theories as to what comprised a good salesperson (e.g., Link, 1932, 1938; Nixon, 1931, 1942; Snow, 1926; 1929). Indeed, Nixon’s bibliography in his second edition of his *Principles of Selling* (1942) lists over a hundred books on the topic. Applied industrial psychologists had reported numerous studies correlating traits, interests, intelligence, and demographic factors with objective measures of performance like total sales (e.g., Freyd, 1922; Craig, 1933; Dodge 1938a, 1938b). An example of this type of study was conducted by the Psychological Corporation and reported by Schultz (1934). Schultz described results from a study in which sale personnel were measured on the traits of ascendance/submission (measured by Beckman’s revision of the Allport Ascendance-Submission Test), and introversion/extroversion (measured by the Root Introversion-Extroversion Test). Intelligence, interests, and general demographic factors were also assessed. Level of ascendance and extroversion correlated with performance. Intelligence screened out “poor” performance but was not related to best or average performance. Age, education, experience, race, and length of service did not reveal any appreciable differences. Interestingly, the employment of E. K. Strong’s Vocational Interest survey generated mixed performance results, identifying individuals that were among the best as well as the poorest performers.

In 1937, McKinney developed a strategy for rating sales messages. Developing two scripts of the sales “interview” partialled into message segments, student evaluators rated each segment as to their perceived value on a 10-point scale from “poor” to “excellent”. Mitchell and Burt (1938) extended McKinney’s work by comparing four pairs of contrasting appeals: 1) demonstration versus oral elaboration; 2) presentation of facts versus short appeals; 3) a “breezy” versus a dignified approach; and 4) a domineering versus a friendly approach. Results favored the demonstration, presentation of facts, and a friendly approach. There was no difference between “breezy” and dignified approaches.

Arthur Dodge (1938a, 1938b) conducted studies testing multiple facets of personality against salesperson performance. Compared to poor salespeople, better salespeople tended to report themselves as less moody, more self-sufficient and self-confident, more aggressive and more willing to assume responsibility, less self-conscious, more social, less desirous of talking about self, less resentful of criticism or discipline, and more radical and unconventional. Hampton (1940) found similar results for small grocer retailers. While these studies suggested these personality variables reflected tendencies of salespeople, none boasted what would be termed “strong” differences.

FOCUS ON RESEARCH METHODS

Although by the mid 1920s there existed several methods in the study of response to advertising, two appeared to be most popular: recall and tests of association (recognition). Indeed, Poffenberger stated “as there are numerous brands of the commonly used articles that really differ little in quality, it is largely a matter of obeying the laws of recall that determines which particular brand shall be bought” (quoted in Lucas & Benson, 1930a, p. 219). Hotchkiss and Franken (1927), in their book entitled *The Measurement of Advertising Effects*, used tests of association and usage to demonstrate the public’s familiarity with different brands of commodities. This work replicated the earlier work of Donovan (1924) by also examining the association of commodities with brands, and the subsequent work of Asher (1928) that revealed a correlation between newspaper advertising expenditures and recall of certain types of retail stores (e.g., drug stores, ladies’ stores, real estate companies, automobile agencies) but not other stores (shoe stores, restaurants, music stores, jewelry stores). One of the benefits to practitioners derived from this method is the ability to focus on competitor influences.

Significant criticism of research methods arose during this period. Using a method of triple associates (as reported by Link, 1934), experiments were conducted by the Psychological Corporation employing 14,000 consumers and conducted by 60 examiners. Hathaway and Welch (1934) questioned the amount of guessing that occurred during this procedure. Link (1932 article cited in McNamara 1941) questioned whether advertisements tested under artificial conditions or with subjects who were arguably not the target of the product promotion provided a valid test. Earlier Poffenberger (1925) questioned whether studies were holding other factors constant like form of layout, quality, and such. Lucas (1937) questioned the inability to control for influence of past ads in present copy testing, suggesting that it was likely impossible to rule out the cumulative effects of similar copy. Gaudet & Zients (1932) suggested that content analyses conducted at certain intervals could not rule out cycling effects that might not be detected with a linear increase. During this time period, treatises began to appear on the types and combinations of questions to ask to ascertain psychological insights into marketing related behaviors (i.e., purchase rationale, advertising effectiveness, post-purchase evaluation) (Lazarsfeld 1934; Kornhauser & Lazarsfeld, 1935). Several individuals suggested improved methods for understanding the impact of radio advertising (Likert, 1936; Gaskill & Holcomb, 1936).

With these criticisms came other new methods of inquiry. Ruckmick (1939) found that respondents’ arousal levels as a reflection of varied advertising, could be measured through detecting sweat gland activity. He found that 3-second exposures to print ads across a repeated series, revealed a relatively consistent pattern. Karlake (1940) presented a study employing a new technique called the Purdue Eye Camera. He compared results employing objective attention measures from the camera against reported results in surveys and found minimal correlation, contending that attention scores resulting from a camera are more accurate than self-reported attention scores.

D. B. Lucas (1940) voiced concern regarding the validity of examining recognition of specific advertisements apart from the context in which the advertising appears. Indeed, he noted the potential for false recognition rates based on a person’s familiarity with other similar ads for the same product. Teaching at New York University, Lucas developed a continuing study of magazine readership of four weekly magazines and created a corrected recognition formula that accounted for false recognition scores. His method was based on exposing respondents to pre- and post-publication exposure advertising. As noted in this chapter, Lucas published multiple studies over the course of 2 decades and his research contributed significantly to knowledge of advertising response at that time. He became the first technical director for the Advertising Research Foundation (ARF).

Welch (1941) recommended that ad copy testing employ four known scales as a system of measurement rather than rely on any one scale. These four measures consisted of brand familiarity (Geissler 1917; Hotchkiss & Franken 1923, 1927), brand preference (Link 1932; Laird cited in Poffenberger 1932; Market Research Corporation of America 1935), theme familiarity (from Link's triple associates test (Link 1932, 1934), and theme credence (Link 1932; Market Research Corporation of America, 1937).

In 1941 and 1942 the *New York Times* ran split-run copy tests providing an opportunity to reply and obtain a free sample. Employing similar ads advertising "False Teeth" or "Dental Plate," in both cases "False Teeth" was slightly stronger in number of replies. Zubin and Peatman (1945), citing these studies, developed and tested a more statistically valid method for using split run copy testing data. They concluded by offering a number of important assumptions to include the randomness of the samples drawn from the population, equal numbers of potential buyers of the product, the availability and inclusion of the maximum size of the sample of potential buyers, and that clipping the coupon is a direct result of the advertisement and not some other factor.

FOCUS ON PREFERENCE

Several researchers during this period addressed how consumers were reacting to various packaging types, primarily as viewed in the size and shape of glass containers. In an earlier book published in 1928, Franken and Larrabee reviewed initial thoughts about packaging and a procedure to consider packaging preference. Employing an accepted method from Franken and Larrabee (1928), Hovde (1931) conducted a controlled field study to find the "best all-around" glass container. He employed multiple examples of caviar and herring containers representing two sizes, 4 oz. and 10 oz. The study was conducted in grocery stores in Philadelphia, beginning with 70 women and 30 men. It is interesting to note that Hovde kept adding groups of respondents to the initial sample until the results became consistent. Hovde began by instructing potential respondents as to the necessity of finding a container that allowed for complete extraction of what was contained inside. His first question sought to address attention value by inquiring as to "which container your attention is most forcibly drawn." Ranking every container employing an order of preference method, respondents were also asked for their reasons for their selection. A second question sought to uncover degree of identification by measuring which container could best be remembered if one forgot the trade name.

In one of the first studies on consumption and children, Guest (1942, 1944) surveyed over 800 school children from 3rd grade through the senior year in high school to assess degree of loyalty to brands versus product class. His results revealed that 1) brand loyalty was stronger than product class loyalty, 2) children form loyalty to brands at an early age, and 3) loyalty evolves and strengthens over time.

FOCUS ON MOTIVATION

The focus on consumer motives began to take hold in the United States with the hiring of Viennese psychologist Ernest Dichter by the Gatchell agency in 1940 (see Allen 1941). Dichter sought clues into human motivation by questioning selected "indicator groups," individuals who would be proactive in providing insights into product usage. Dichter used this information to provide a "psychological inventory" of basic motives for specific product purchases. This information in turn, would help advertising creatives develop messages that would directly address the customer motives (a fuller description of Dichter's contribution appears in the next section).

In 1941, Allen authored an article that applied Allport's (1937) notion of functional autonomy to better understanding consumer motives. In this paper, Allen presents a list of "primary wants" that are more direct (e.g., appetizing food, comfortable surroundings, welfare of loved ones, social approval, play) and "secondary wants" that are more removed (e.g., health, convenience, cleanliness, style/beauty, dependability/quality). Allen provides examples of typical product/service appeals that would provide the linkage between product/service and motive.

In the years leading up to World War II, numerous European scholars like Lazarsfeld, Dichter, and Politz (the European pollster) fled from their home countries to the United States and to American universities or industry. The nature of consumer research was also changing as former academics like George Gallup and Daniel Starch pioneered the profitable marketing research industry.

THE EARLY YEARS AFTER WORLD WAR II

During the final phase of this review (post-World War II–1960), we return to two major contributors to the discipline of consumer psychology and a number of smaller, but nonetheless, important players.

Ernest Dichter

Considered by many a founding father of motivational research, Ernest Dichter was born in Vienna in 1907 and lived across the street from Sigmund Freud's famous office. Dichter discovered early he had a strong interest in psychology. After completing his doctoral studies, he began his career as a practicing psychoanalyst. Indeed his dissertation topic was a "self-appraisal of one's own abilities." He soon found his way to work under Paul Lazarsfeld's Vienna centre for industrial research. Dichter immigrated to New York in 1937 where he quickly found he was invited to consult with major companies about his insights into the psychology of the consumer.

Dichter was quite controversial. Denouncing all marketing research except his own as "nose-counting and "census-taking" (Fullerton & Stern, 1990, cited in Kassirjian, 1994), he became a highly vocal proponent of his own methodology which relied heavily on Freudian psychology (Stern, 2004). Indeed, his own mentor, Paul Lazarsfeld became one of his harshest critics, along with researchers Gallup, Politz, and the Marketing discipline's Wroe Alderson (Ferber & Wales, 1958; Kassirjian, 1994)

To better understand human motivation, Dichter employed in-depth interviews and projective techniques to tap both conscious and subconscious states thought to guide the behavior of the consumer. He felt that his background in psychoanalysis provided him with insights into hidden motives behind purchasing behavior. From this understanding, he was able to work with advertisers to create impactful brand slogans— "Wash your troubles away" for Procter & Gamble's Ivory Soap. From 1943 to 1946 Dichter was employed by the Columbia Broadcasting System (CBS).

In 1946, Dichter founded his Institute for Motivational Research on the Hudson River just north of New York City. A *Harvard Business Review* article (Dichter 1947) reflected his belief that past methods only scratch the surface and that advertising and personal selling have dynamic effects on the consumer. He also pointed out the importance of multiple motives and reflects that Freud's multiple levels of consciousness provide reason for the importance of "modern" (qualitative) psychological methods. Dichter (1948) also employed multiple techniques (i.e., depth interviewing, role playing, sociometric maps) to discover what he termed the "real" reasons are behind brand purchasing.

Vance Packard's *The Hidden Persuaders* (1957) made Dichter a household name, suggesting that Dichter was the master manipulator of the consumer mind. Packard brought Dichter a significant amount of fame and fortune, creating a significant corporate demand for his consulting services. He published several books, with the *Handbook of Consumer Motivation* (1964) perhaps the most popular and most widely cited. It is important to note that Dichter's research went far beyond just the study of the consumer. His work also reflected the study of human motives behind topics like voter participation, religious tolerance, and racial prejudice. Dichter, always the business man, founded multiple research institutes in Europe as well the Hudson River Institute. Many of these are still active today.

George Katona

George Katona is considered to be the dean of behavioral economics. After receiving a degree in law from the University of Budapest, he received his PhD in Germany under Georg Elias Nathanael Muller at Göttingen in 1921 following in the tradition of Wundt and Titchner. He came to the United States in 1933 and started employment as an investment counselor. In 1936, he began lecturing at the New School for Social Research and was heavily influenced by his colleague, the Gestalt psychologist Max Wertheimer. Wertheimer (and other Gestalt psychologists), along with Watson's behaviorism and Freud's dynamic approach, had begun to successfully turn psychology away from the experimental work that followed the tradition of Wundt and Titchner (Boring, 1950). In 1945, Katona joined the faculty at the University of Michigan.

Katona, along with Likert, Campbell and others, founded Michigan's Business Survey Research Bureau, and he became the director of the economic behavioral program. His pioneering achievement was in the application of consumer psychology to economic forecasting. In contrast to existing economic theory that relied chiefly on factual demographic driven input (e.g., income, ability to buy), Katona believed that a consumer's willingness to buy, as denoted by the consumer's attitudes and expectations (his view of consumer psychology), was a critical economic indicator.

Katona authored numerous articles during his lifetime and published more than a dozen books including *The Powerful Consumer* (1960) and *The Mass Consumption Psychology* (1964). These books contained his caution to other economists as well as practitioners against stereotyping consumers as having simplistic motives and being easily manipulated. Perhaps Katona's most enduring legacy was his initiation of the Survey of Consumer Attitudes for the University of Michigan Institute for Social Research, today employed as a major indicator of economic stability of markets.

THE CONTRIBUTION OF OTHERS DURING THIS PERIOD

Immediately following the war came an emphasis on consumption by U.S. citizens who had just experienced several lean years of sacrifice. An explosion of manufacturing and new products led to new applied questions; for example, could the consumer discriminate in taste for food and drink. Pronko and Bowles reported three studies investigating whether drinkers of colas could discriminate between brands (Pronko & Bowles, 1948, 1949; Bowles & Pronko, 1948). It is not clear whether they gave respondents varied strategies for taste testing, but the results consistently reflected that there was no consistency in consumer discrimination of brands of cola.

Another important question that emerged during this time was based on the need to determine why consumers patronized certain retail stores. Heidingsfield (1949) surveyed patrons of downtown Philadelphia department stores to ascertain the motives for store selection. In rank order the factors included the nature of merchandise, prices, physical factors, and service. Blankertz (1949)

reports a similar study by a group at his own university, but challenges both of these studies on issues of methodology. He provides several examples such as the notion that attitudes are relatively weak reflections of other important contributing factors like distance. He also argued against the wisdom of depending on attitude scores given their lack of ability to predict store expenditures, and the belief that reports of attitudes may reflect rationalization rather than other internal states (e.g., affect).

In 1950, Mason Haire published his famous article in the *Journal of Marketing* that called into question people's willingness to share their real responses. With the advent of instant coffee and consumers' reluctance to adopt it, studies suggested that taste was the reason. However, Haire was skeptical of this finding and designed a projective test to see if there were other underlying reasons. He employed two groups of homemakers, both of whom were provided with a shopping list. All the products on the list were held constant except that one list contained Nescafe Instant Coffee while the other contained "1 lb. Maxwell House Coffee (Drip Ground)." He then asked his two sample segments to describe a person who would be shopping for these products. The respondents with the Maxwell House Coffee on their list consistently described the person in more positive terms (e.g., housewife, concerned about what she served her family) than did those who received the list with Nescafe Instant Coffee (e.g., single woman living from one day to the next). There was no indication that taste was a factor. The real reason had much more to do with how a person using instant coffee would be perceived.

In 1952, Dik Twedt from Northwestern University conducted a survey study of 34 variables believed to be related to magazine readership scores. Prior to this, there were a number of individuals, including James D. Woolf, formerly the vice-president of the J. Walter Thompson advertising agency, claiming that content, rather than mechanical factors, were what pulled individuals to read ads (Woolf, 1951, see also earlier study by Ferguson, 1935). Using a popular trade magazine, Twedt's study actually revealed that a significant portion of explained variance for readership was due to three mechanical factors, size of advertisement, number of colors, and square inches of illustration. It is also of interest that Dik Twedt (1965) authored the first review of Consumer Psychology that appeared in the *Annual Review of Psychology*.

CONCLUSION: HOW CONSUMER PSYCHOLOGY HAS EVOLVED

This chapter sought to bring out two points of emphasis regarding the roots of consumer psychology. First, consumer psychology has evolved as the larger domain of general psychology has evolved. This is evident in the transition of schools of thought, from the early mentalist approach of Wundt and his students, to a rejection of mentalism in favor of behavioral and dynamic approaches. These schools are all important in the investigation of consumer behavior as we research it today. The second point of emphasis is the fact that these early psychologists built upon each other's work, and that many of the topics they studied are those that we're still engrossed with today and expect to be for many years to come.

It's hard to know what psychological discipline "owned" consumer psychology. In developing the sketches of these pioneers, it was apparent that they viewed themselves as "applied" psychologists. The words "industrial" and "organizational" psychologists rarely appeared. However, because the broader interests of individuals like Munsterberg, Scott, Strong, and Poffenberger, who, as a group, moved far beyond a singular focus on advertising and selling response, the study of the consumer was brought into the larger framework of the study of business. Thus consumer psychology for many years, certainly through the 1950s, was labeled a part of Industrial/Organizational Psychology.

In the late 1950s an informal group of applied psychologists known as the “headshrinkers” came into existence in Chicago (Kamen, 1995). The group consisted of applied psychologists primarily working for advertising agencies, polling companies, and marketing research firms. They met on a regular basis and before long they included academics in their meetings. Finally in 1959, they decided to approach the APA to initiate a new division and Division 23 of APA, the Division of Consumer Psychology, was born. Dik Twedt was the first President of the Division of Consumer Psychology and Clark Leavitt was the second President. Today, with a membership of over 600 and a sponsored scholarly periodical, the *Journal of Consumer Psychology*, the Society for Consumer Psychology symbolizes the independence of this growing discipline. Nevertheless, the history of consumer psychology will always be indebted to the early “applied psychologists.”

CONSUMER INFORMATION PROCESSING

2

The Role of Knowledge Accessibility in Cognition and Behavior

Implications for Consumer Information Processing

ROBERT S. WYER, JR.

Hong Kong University of Science and Technology

People's judgments and decisions are typically based on only a small subset of the knowledge they could potentially apply. Furthermore, when they receive new judgment-relevant information, they construe its implications without considering all of the alternative interpretations it might have. The concepts and knowledge they employ in each case are not necessarily either the most relevant or the most reliable, but rather, are the cognitions that come most easily to mind. This general tendency, which has been documented at all stages of information processing from the initial acquisition and comprehension of information to the generation of an overt response, is one of the most widely accepted phenomena to emerge in the past three decades of psychological research (Bargh, 1997; Higgins, 1996; Wyer, 2004). Nowhere is its importance greater than in the domain of consumer judgment and decision making. That is, purchase decisions, like judgments and behavior more generally, are often based on whatever criteria happen to be salient at the time.

Because of its pervasiveness, the role of knowledge accessibility is a central component of almost every theoretical formulation of social information processing to appear in the past three decades, ranging from general formulations of judgment and behavior (Bargh, 1997; Carlston, 1994; Smith, 1990; Wyer, 2004; Wyer & Srull, 1989) to more specific formulations of attitude formation and change (Chaiken, 1987; Petty & Cacioppo, 1986), attitude-behavior relations (Fazio, 1990), impression formation (Higgins, Rholes, & Jones, 1977; Srull & Wyer, 1979), stereotype activation and suppression (Bodenhausen & Macrae, 1998), the effects of the media on perceptions of social reality (Shrum, 2002), the impact of affect and subjective experience on judgments and decisions (Schwarz, 2004; Schwarz & Clore, 1996; Strack & Deutsch, 2004), goal-directed behavior (Chartrand & Bargh, 2002), cultural influences on behavioral decisions (Briley & Wyer, 2002; Hong, Morris, Chiu, & Benet-Martinez, 2000), and perspective effects in judgment (Adaval & Monroe, 2002). In the area of consumer research, the role of knowledge accessibility is implicit if not explicit in research on subliminal advertising (Moore, 1982, 1988; Trappey, 1996; see also Vargas, this volume), brand awareness (Kardes, Gurumurthy, Chandrashekar, & Dronoff, 1993), pricing (Adaval & Monroe, 2002), and product evaluation more generally.

Extensive reviews of theory and research on knowledge accessibility are available elsewhere (Higgins, 1996; see also Bargh, 1994, 1997; Förster & Liberman, in press; Wyer, 2004), and we will not repeat this material unnecessarily. The first section of this chapter reviews alternative

conceptualizations of knowledge accessibility phenomena, drawing largely from research and theory in cognitive and social psychology. Later sections provide examples of the role of knowledge accessibility at several different stages of information processing, including the attention to and comprehension of information, the representation of the information in memory, the computation of inferences on the basis of previously acquired knowledge, and behavior decisions. In the course of this discussion, we review representative research and theory in consumer judgment and decision-making in which differences in knowledge accessibility come into play.

GENERAL CONSIDERATIONS

Stages of Information Processing

The processing of information for the purpose of making a judgment or decision can occur in several stages. For example:

1. Attention—people pay differing amounts of attention to the various aspects of the information they receive.
2. Encoding and comprehension—people interpret individual pieces of information in terms of previously formed concepts that they exemplify, and may organize clusters of features with reference to a more general knowledge structure or “schema.” Thus, they might interpret a \$70 pair of jeans as expensive, or comprehend a temporally related sequence of events that occur at a restaurant in terms of a prototypic “restaurant script” (Schank & Abelson, 1977).
3. Inference—people often infer the likelihood that a statement or assertion is true, or the frequency with which a particular event has occurred. At the same time, they estimate the likelihood that an event will occur in the future, or that a certain state of affairs did or does exist. They sometimes infer that an object has a particular attribute, or might evaluate it as either favorable or unfavorable. In other cases, they make a comparative judgment of several objects or events along a given dimension, or might compute a preference for one alternative over another.
4. Response processes—people transform the implications of their subjective judgment into an overt response or behavioral decision.

Processing at each of these stages typically requires the activation and use of previously acquired concepts and knowledge. Therefore, it may depend in part on which of several potentially relevant subsets of this knowledge happens to be most accessible.

TYPES OF KNOWLEDGE REPRESENTATIONS

The knowledge that comes into play at these stages of processing can be of two general types. *Declarative* knowledge concerns the referents of everyday life experiences (persons, objects, events, attitudes and values, oneself, etc.). In contrast, *procedural* knowledge refers to the sequence of actions that one performs in pursuit of a particular goal (driving a car, using a word processor, etc.) Whereas declarative knowledge is reflected in the information we can recall about an entity or that we implicitly draw upon in the course of attaining a particular objective, procedural knowledge is reflected in the sequence of cognitive or motor acts that are performed in the pursuit of this objective. People can, of course, have declarative knowledge about how to attain a particular objective, and might sometimes consult this knowledge for use as a behavioral guide. Once the procedure is

well learned, however, it may often be applied automatically, with little if any conscious cognitive mediation.

These automated procedures can be conceptualized as “productions” of the sort suggested by J. R. Anderson (1982, 1983; see also Smith, 1990, 1994). Thus, they may be metaphorically have the form of “If [X], then [Y]” rules in which [X] is a configuration of perceptual or cognitive stimulus features and [Y] is a sequence of cognitive or motor acts that are elicited automatically when the eliciting conditions are met. These productions, which are acquired through learning, are strengthened by repetition, and can ultimately be activated and applied with minimal cognitive mediation. The routines involved in driving a car (e.g., putting in the clutch, turning on the ignition, putting the car in gear, gradually releasing the clutch while stepping on the gas, etc.) initially require conscious thought. However, they ultimately come to be performed without consulting declarative knowledge about the sequence of steps involved, and require few if any cognitive resources (Schneider & Shiffrin, 1977). As Bargh (1997) argues, a very large amount of our social behavior is likely to involve the use of these automatically activated productions.

The influence of both declarative knowledge and procedural knowledge is apparent at all of the aforementioned stages of processing. Many effects that are attributed to the accessibility of declarative could be due to the accessibility of procedural knowledge instead. In this chapter, we focus primarily on the accessibility of declarative knowledge (Smith, 1990). Nevertheless, the accessibility of procedural knowledge is likely to have a particularly important impact on overt behavior as will be seen.

Declarative knowledge can consist of general semantic concepts (honest, woolen, etc.) or categories (lawyer, Irishman, high-tech, designer jeans, etc.) Alternatively, it could comprise a configuration of features that are organized temporally, spatially or causally and are stored in memory and later retrieved as a unit. These knowledge representations could pertain to a specific person or experience (e.g., George W. Bush, the 2004 Super Bowl game, my trip to Bermuda in 1985, last night’s dinner at Jaspa’s Restaurant) or a more general characterization that applies to several individuals or events (reactionary politicians, football games, vacation trips, restaurant visits).

Representations of a situation-specific sequence of events may constitute a story (Schank & Abelson, 1995). However, more generalized sequences of events can function as *implicit theories* that convey the antecedents and consequences of different types of experiences involving oneself or others (Dweck, 1991; Dweck, Chiu, & Hong, 1995; Ross, 1989; Wyer, 2004). These representations come into play in not only comprehending new experiences but also reconstructing past events and predicting future ones. Other generalized event sequences can constitute plans or procedures that are used as behavioral guides in attaining a particular goal.

The knowledge representations that people construct can be coded in different modalities. Although much of our knowledge is coded verbally, a very large portion of it (particularly the knowledge we acquire through direct experience) is nonverbal, consisting of mental images that have both visual and acoustic components (Wyer & Radvansky, 1998).

Finally, the knowledge we acquire can elicit subjective reactions (e.g., positive or negative affect) that, once experienced, can exert an influence on the processing of information at each of the stages listed earlier. These reactions, once elicited, can be a major source of the information people use as a basis for judgments and decisions (Schwarz & Clore, 1996; Strack & Deutsch, 2004). On the other hand, they can influence the interpretation of information (Adaval, 2003; Isbell & Wyer, 1999), and the weight that people attach to it when making a judgment (Adaval, 2001). Although affect, or subjective experience more generally, is not itself a part of the knowledge one stores in memory, it can be elicited by this knowledge (Wyer, Clore, & Isbell, 1998). Its influence can nevertheless be

conceptualized in terms very similar to that of other aspects of knowledge that people have accessible at the time they receive information and make a judgment or decision.

Despite these differences in the content and structure of knowledge, the processes that govern its accessibility in memory are similar. In the next section, we propose a set of principles that describe these processes. These principles potentially apply at all stages of processing.

BASIC PRINCIPLES

Several theories of information processing purport to account for the determinants and effects of knowledge accessibility (e.g., Higgins, Bargh, & Lombardi, 1985; Smith, 1990; Wyer & Carlston, 1979; Wyer & Srull, 1989; Wyer, 2004). Although these theories often make different specific assumptions about the mechanisms that underlie memory storage and retrieval, they agree that the knowledge one retrieves and brings to bear on the processing of information is a function of its association with the thoughts and concepts that happen to be activated at the time the knowledge is sought. The cognitions that cue its retrieval can include aspects of the information to be processed and the situational context in which it is presented. They can also be internally generated. For example, people who wish to purchase a car may intentionally retrieve a set of attributes that characterize a high quality automobile and use the attributes as guides in construing the implications of information about a particular car they are considering. In many cases, however, thoughts that one has recently had for another, objectively irrelevant purpose can also cue the retrieval of knowledge from memory.

A fairly large number of concepts and knowledge representations can often be associated with a given set of retrieval cues, and people are usually neither able nor motivated to consider all of them. This observation leads to the most fundamental principle on which theory and research on knowledge accessibility is based:

Principle 1. People rarely retrieve and use more knowledge than is necessary to attain the objective they are pursuing. When each of several knowledge representations is sufficient to attain this objective, the first representation that comes to mind is most likely to be applied.

This means that if two or more different concepts or knowledge representations can be used to attain a particular goal, the one that is identified and applied most quickly and easily will be employed. For example, suppose to attribute concepts, “tasty” and “unhealthy” are equally applicable for interpreting information that a drink has artificial sweeteners. In this case, the one that comes to mind first is most likely to be applied. Similarly, if several criteria (e.g., brand name, specific attributes) are potentially available for evaluating a product, the criteria that can be applied most easily are most likely to be considered.

Principle 1 does not necessarily imply that the first knowledge that comes to mind is the *only* knowledge to be employed. This is true only if it is deemed sufficient to attain the objective one is pursuing. Chaiken (1987; Chaiken, Liberman, & Eagly, 1989) assumed that people who process information for a particular purpose first invoke the criterion that they can apply most quickly and easily and evaluate their confidence that the results of applying it is sufficient to attain the objective they are pursuing. If their confidence is above a minimum threshold, they use it without further ado. If their confidence is below threshold, however, they apply the next most accessible criterion, and continue in this manner until their threshold is reached. The threshold that individuals apply in any given situation can increase with the importance of the goal to which the processing is relevant. It can also depend on the time and effort the person is able to devote to this activity. Therefore,

the less motivated people are to engage in extensive cognitive processing, or the less time they have available, the more likely they are to use the first criterion they consider to the exclusion of others.

The sufficiency principle has broad applicability, and versions of it can be found in diverse theories of judgment, including the conception of satisficing (Simon, 1955) and the impact of affect on judgment (Schwarz & Clore, 1996). Its importance is apparent throughout this chapter.

DETERMINANTS OF KNOWLEDGE ACCESSIBILITY

Most theories agree on four determinants of knowledge accessibility: (1) the strength of association between the knowledge to be accessed and concepts that have already been activated in the situation at hand, (2) the recency with which knowledge has been acquired and used, (3) the frequency with which it has been employed, and (4) the amount of processing in which it has been directly or indirectly involved.

Strength of Association

As noted earlier, the accessibility of knowledge in memory at any given moment is determined in part by the strength of its association with situational, informational, or internally generated features that exist at the moment and, therefore, serve as implicit or explicit retrieval cues. These associations may be either semantic or experience-based. Thus, for example, the word “bread” might cue the retrieval of “butter,” and a picture of a yellow double arch is likely to stimulate a concept of McDonald’s. The retrieval of such associated cognitions may be a conditioned cognitive response to the stimulus concept or cognition that is acquired through learning in much the same way as other, noncognitive responses. In many instances, however, the features of a stimulus are associated to a similar extent with more than one concept or unit of knowledge. In this case, other factors come into play.

Recency and Frequency

When two concepts or knowledge units are equally useful in attaining a particular processing objective, the one that has been used more recently in the past is likely to be applied again. This effect was first identified in social psychology by Higgins, Rholes, and Jones (1977). They showed that unobtrusively exposing participants to a trait concept while they performed an ostensibly unrelated “priming” task* increased their use of this concept to interpret the information they later received about a fictitious target person and, consequently, influenced their liking for this person. These effects have been identified even when the concepts are primed subliminally (Bargh & Pietromonaco, 1982).

The accessibility of knowledge can also be determined by the frequency with which a unit of knowledge has been activated and used in the past (Higgins et al., 1985; Srull & Wyer, 1979). Frequently encountered concepts and knowledge can become *chronically* accessible in memory (Higgins, King, & Mavin, 1982) and, therefore, can have effects independently of situational factors that might activate them (Bargh, Bond, Lombardi, & Tota, 1986). The cognitive processes that theoretically underlie the effects of frequency of use and the effects of recency of use may differ (cf. Higgins et al., 1985; Wyer, 2004; Wyer & Srull, 1989). Consequently, these factors may contribute independently to their overall accessibility in memory (Bargh et al., 1986). However, although the

* In this chapter, we use the term “priming” to refer to an experimental procedure that is used to increase the accessibility of a unit of knowledge in memory, as distinct from the accessibility of the concept itself.

effects of recently activated concepts initially override the effects of frequency, they are short-lived. Consequently, the effect of frequency predominates after a period of time has elapsed (Higgins et al., 1985). To summarize:

Principle 2. The accessibility of a unit of knowledge in memory is an increasing function of both the recency with which it has been activated in the past and the frequency with which it has been activated. The effect of recency decreases over time, whereas the effect of frequency persists.

The similar effects of recency and frequency of activation are of methodological importance. That is, hypotheses concerning the effects of chronically accessible concepts and knowledge can be confirmed indirectly by establishing the effects of recently activating them in a laboratory context. (For examples of the use of this strategy, see Schwarz & Strack, 1981; Shrum, Wyer, & O'Guinn, 1998; Wyer, Bodenhausen, & Gorman, 1985.)

Amount of Processing

The accessibility of knowledge in memory can also be influenced by the extent to which the knowledge was thought about at the time it was first acquired (Craik & Lockhart, 1972; Wyer & Hartwick, 1980). Several specific mechanisms could underlie these effects (Anderson, 1983), including the reconstructive processes outlined elsewhere in this handbook (Kronlund et al., this volume; for a specific empirical application of the role of reconstructive inference to brand memory, see Noel, 2006). In some cases, the impact of amount of processing might not be independent of the influence of frequency or alternatively, strength of association. That is, the greater the amount of cognitive activity that is devoted to a piece of information, the greater the number of cognitive elements with which is likely to become associated and the greater the number of knowledge units in which it is embedded. Nevertheless, its influence on knowledge accessibility is worth noting in its own right.

EFFECTS OF PRIOR JUDGMENTS ON SUBSEQUENT ONES

One manifestation of the effects of recency of knowledge activation is worth special consideration. Once an implicit or explicit judgment has been made on the basis of information received at one point in time, a representation of this judgment can often be stored in memory independently of the information that led to its construction. Consequently, the judgment may later be retrieved out of context and used as a basis for other judgments and decisions (Carlston, 1980; Higgins & Lurie, 1983; Sherman, Ahlm, Berman, & Lynn, 1978; for evidence in the consumer domain, see Kardes, 1986). This means that if situationally primed knowledge influences the representation that is formed of information and this representation is stored in memory, its influence is likely to persist over time.

As one example, participants in a study by Srull and Wyer (1980) first performed a sentence construction task in which a concept of hostility was activated. Then, they read a paragraph describing a target person whose behavior was ambiguous with respect to hostility with instructions to form an impression of the person and later judged the target with respect to this attribute. However, the time intervals between the sentence construction task, the target information, and judgments were varied. When trait concepts were primed 24 hours before the ambiguous target information was presented, they had little effect. When the concepts were primed immediately before participants received the target information, however, they had a positive effect on judgments. Furthermore, their effect was significantly greater 24 hours after the information was presented than it was immediately afterwards.

Principle 3. If people have interpreted information on the basis of recently activated concepts and knowledge, the effects of this interpretation on later judgments and decisions about its referent will persist over time.

A corollary of this principle is that once people have formed a mental representation of a stimulus, concepts that become accessible subsequently are likely to have little effect on the judgments they report later. In other conditions of Srull and Wyer's (1980) study, hostility-related concepts were primed immediately after participants had read the target description rather than beforehand. In this condition, participants presumably interpreted the target's behavior in terms of whatever concepts happened to be accessible and formed an impression on the basis of this interpretation. They later based their judgments on this impression, and concepts that were activated subsequent to its construction had no impact.

Darley and Gross (1983) reported analogous findings. That is, information about a child's socio-economic background influenced participants' judgments of the child's ability if it was conveyed before the participants saw a videotape of the individual's performance on an exam. However, it had no impact on judgments if it was not conveyed until after the tape was viewed. Similarly, Yeung and Wyer (2004) found that if participants were induced to feel happy or unhappy before they encountered a picture of a product, they used their affective reactions as a basis for their initial impression of the product and this impression influenced their later evaluations of it independently of the attribute information they received subsequently. On the other hand, if participants' affective reactions were not induced until after they had seen the picture and formed an impression on the basis of it, the affect they were experiencing had no influence on their product evaluations.

It is nonetheless important to note that the interpretation of information in terms of recently activated trait concepts does not always occur spontaneously. Rather, it may only occur when people have a specific goal in mind that requires the application of these concepts (e.g., forming an impression of the object that the information describes). If people process the information with no particular goal in mind, they may not spontaneously engage in this cognitive activity (Wyer, 2004). In this case, the accessibility of concepts and knowledge at the time of judgment is more likely to exert an influence.

THE INFLUENCE OF AWARENESS ON THE IMPACT OF ACCESSIBLE KNOWLEDGE

People can be influenced by information that they do not know they have received. Bargh and his colleagues (for reviews, see Bargh, 1994, 1997) have identified these effects at several different stages of processing. For example, subliminally presented trait concepts can influence people's interpretation of information about a target person's behavior and, consequently, judgments of this person (Bargh & Pietromonaco, 1982); subliminally primed evaluative-toned concepts can affect the ease with which participants identify other words that are evaluative similar or dissimilar (Bargh, Chaiken, Raymond, & Hymens, 1996; Bargh, Chaiken, Govender, & Pratt, 1992). Subliminally priming high or low numbers can influence people's judgments of the expensiveness of a product they are later asked to evaluate (Adaval & Monroe, 2002), and subliminally exposing people to faces of a stereotyped group can influence the likelihood of behaving in ways that are characteristic of that group (Bargh, Chen, & Burrows, 1996).

Corrections for Bias

Even when people are exposed to information overtly, they may not be aware of its possible effect on their judgments in other, ostensibly unrelated situations. People are likely to assume that the

concepts and knowledge that come to mind when they think about a stimulus are activated by this stimulus alone. Consequently, they are likely to consider the implications of these cognitions to be representative of the knowledge they have available about the stimulus and, therefore, to be an appropriate basis for judgments and decisions they might make concerning it. Only if they are aware that the knowledge that comes to mind might be biased, will they try to correct for this influence.

In such cases, they might discount implications of the knowledge entirely and search for alternative criteria to use. Lombardi, Higgins, and Bargh (1987), for example, found that when participants were able to recall the priming words to which they had been exposed (suggesting that they were aware of their possible influence), they were actually *less* likely to use the primed concepts to interpret the stimulus information than they otherwise would have been. In some instances, however, participants may believe that their interpretation of information might be biased but are either unmotivated or unable to correct for it. In a series of studies by Martin, Seta, and Celia (1990), for example, participants were clearly aware that the concepts they had employed in an ostensibly irrelevant task could influence their interpretation of the information they received subsequently. In these conditions, the primed concepts only had a positive influence on their judgments when participants were either unable to devote the cognitive effort required to identify and use a different concept (e.g., under high situational distraction) or, alternatively, were unmotivated to expend this effort (e.g., they were low in need for cognition, or felt little personal responsibility for the judgments to be made).

In a particularly intriguing demonstration of these contingencies, Martin (1986) primed trait concepts using procedures similar to those employed by Martin et al. (1990). However, some participants were ostensibly interrupted before they completed the priming task, whereas others were led to believe they had finished it. (In fact, all participants were exposed to the same number of primes, regardless of whether they were interrupted or not.) Participants who were interrupted apparently continued to ruminate about the task (Zeigarnik, 1938), and this cognitive activity prevented them from searching for alternative concepts to use in interpreting the target information they received subsequently. Thus, the primed concepts had a positive impact on the judgments they made on the basis of this information. When participants believed they had completed the priming task, however, they did not ruminate about it and devoted their cognitive resources to arrive at an unbiased interpretation of the target information. Consequently, the priming effects observed under interrupted-task conditions were not evident.

Rather than searching for alternative judgmental criteria to use, people who believe their judgments may be biased may sometimes find it easier to make a tentative judgment and then to adjust this judgment to compensate for the effects that the judgment-irrelevant knowledge is likely to have had. In this case, however, they may not know how much to adjust. If they do not adjust enough, the knowledge will continue to exert an influence. If they adjust too much, it could have a negative, contrast effect (Ottati & Isbell, 1986). Which effect occurs is likely to depend in part on individuals' implicit theories of the amount of bias produced by the external situational factors in question (Wegener & Petty, 1997; see also Strack, 1992).

Adjustment processes of particular relevance for consumer research were identified by Schwarz and Bless (1992; see also Strack et al., 1993). When people are exposed to items in an opinion survey, questions that occur at one point in the survey may activate concepts that are used as a basis for responses to later questions. However, if respondents are aware of this influence, they may try to correct for it. Indeed, they may believe that the questioner does not intend to ask the same question twice. In this case, they may use different criteria in responding to the questions even if the questions appear related.

Several other studies provide evidence of this effect. Strack, Martin, and Schwarz (1988; Strack & Martin, 1987), for example, asked participants to report their satisfaction with their marriage and also their satisfaction with life as a whole. When the questions appeared on separate pages of the questionnaire, responses to the questions were correlated .55. When the second question immediately followed the first, however, the correlation was reduced to .26. Respondents in the latter case apparently assumed they should use different criteria for evaluating their life as a whole than they used in responding to the first item, and consequently excluded their marriage from consideration.

Similarly, Ottati, Riggle, Wyer, Schwarz, and Kuklinski (1989) found that asking participants their opinions about the rights of a positive or negative social group (e.g., whether the American Civil Liberties Union or the American Nazi Party should be allowed to speak on campus) had a positive influence on their responses to a general question (whether people should be allowed to express their views in public) when the items were separated by six other, unrelated ones. When the group-specific item immediately preceded the general one, however, participants appeared to exclude the group from consideration in responding to the general question. As a result, the group-specific item had a negative, contrast effect on their responses.

The methodological implications of these findings are obvious. In much research on consumer behavior, multiple items are used to assess the same construct (e.g., liking for a product). This is done under the assumption that the use of several related provides a more reliable estimate of the construct of concern. In fact, however, by stimulating participants to use different criteria for responding to the items than they otherwise might, the procedure could often have precisely the opposite effect.

To summarize:

Principle 4. Knowledge that becomes accessible in memory for reasons that are unrelated to a judgment or decision will influence this judgment or decision if participants either are unaware of the conditions that activated the knowledge or, alternatively, are unaware of the relation between these conditions and the judgment or decision to be made. Even if people are aware of the biasing influence of judgment-irrelevant knowledge, they may not be motivated or able to correct for its influence or, alternatively, may not know how much they should adjust their response to compensate for its effect.

The contingencies implied by Principle 4 should not be overemphasized. As we noted earlier, people are unlikely to pay much attention to the extraneous situational factors that influence the knowledge they bring to bear on their judgments and decisions. Rather, they attribute the accessibility of this knowledge to the person or object they are judging. Consequently, the influence of extraneous determinants of knowledge accessibility may be quite pervasive.

The Effects of Thought Suppression on Knowledge Accessibility

People who consciously try to avoid the use of a concept or body of knowledge in interpreting information or making a judgment are often successful. However, active attempts to avoid using a judgmental criterion often require thinking about the criterion to be avoided. The effort expended in an attempt to suppress its use can actually increase its accessibility in memory relative to conditions in which this effort is not made. Consequently, once the restrictions on its use are lifted, the suppressed concept or knowledge may be more likely to be used than it otherwise would.

This possibility, which was identified empirically by Wegner (1994), was applied in an innovative series of studies by Macrae, Bodenhausen, and their colleagues (for a review, see Bodenhausen & Macrae, 1998). In one set of studies (Macrae, Bodenhausen, Milne, & Jetten, 1994), participants

received a picture of a skinhead along with other verbal information and were told to form an impression of the person. However, some participants were told explicitly not to rely on a stereotype in arriving at their impression. Their judgments of the target indicated that the instructions were successful. Nevertheless, they responded more quickly than control participants to stereotype-related words in a subsequent word-identification task. Furthermore, they described a second skinhead more stereotypically once the restriction on the use of this stereotype was lifted, and avoided sitting close to a skinhead while waiting for a later part of the experiment. In short, the active suppression of a stereotype-related knowledge actually increased its accessibility in memory, and this knowledge influenced both later judgments and behavioral decisions once the sanctions against using it were removed.

The four principles summarized in this section typically apply independently of the type of knowledge involved and the type of judgment or decision to which this knowledge is applied. In the following sections, we review representative studies in both psychology and consumer research that bear on the effects of knowledge accessibility at different stages of processing. In this context, we note some additional considerations that arise in conceptualizing the effects at these stages.

ATTENTIONAL PROCESSES

Selective Information Seeking

Individual pieces of information are more likely to be identified and thought about if they can be interpreted in terms of concepts and knowledge that are easily accessible in memory. This may be true even if the other information available is equally relevant to the goal one is pursuing. The concepts that exert this bias could be activated either by the particular goal one is pursuing and by goal-irrelevant situational factors that happen to make these concepts come to mind.

The Effect of Goals on Selective Attention

The bias produced by goal-directed information seeking was demonstrated by Snyder, Swann, and their colleagues (Snyder, 1981; Snyder & Swann, 1978; Swann & Giuliano, 1987). Suppose people wish to decide if a person or object belongs to a certain category (e.g., extrovert, good secretary, high quality DVD player, etc.). To make this assessment, they are likely to activate a set of attributes that characterize members of this category and to search for information that can be encoded in terms of these attributes. At the same time, they may be disposed to ignore information that is not interpretable in terms of category-consistent features.

Thus, for example, people who want to determine if someone is an extravert may activate attribute concepts such as “talks a lot,” “likes parties,” “says hello to strangers on the street,” etc.) and may search for information that can be interpreted in terms of these concepts. In doing so, they may ignore information that is interpretable in terms of attributes that might disconfirm the target’s membership (e.g., “goes for long walks alone,” “avoids large crowds,” etc.) This selective search could produce a bias in the conclusions that are drawn.

Snyder and Swann (1978; see also Swann & Giuliano, 1987) gave some participants the opportunity to select questions to ask a person for the purpose of deciding if the person was an extravert, and gave others the opportunity to select questions to decide if (s)he was an introvert. Participants selected questions that presupposed the attribute they were attempting to evaluate (e.g., “What do you like about parties?”) and, therefore, were likely to elicit answers that confirmed the person’s

membership in the category they were considering (Snyder & Swann, 1978). Alternatively, they selected questions, affirmative answers to which provided this confirmation (e.g., "Do you like parties?") (Swann & Giuliano, 1987).

In another study (Snyder & Cantor, 1979), participants read a paragraph about a person that contained equal amounts of extraverted and introverted behavioral descriptions with instructions either to decide if the person was an extravert or to decide if she was an introvert. They paid more attention to descriptions that confirmed the person's membership in the specific category they were considering, as inferred from both their judgments and the information they later identified as relevant to these judgments.

Initial preferences can operate in much the same way as hypotheses. Chernev (2001), for example, found that participants with an initial preference for a product tended to pay greater attention to information that confirmed their preference than to information that disconfirmed it, thus biasing the effects of the information in the direction of their initial attitude. Similarly, Yeung and Wyer (2004) found that consumers who had formed an initial impression of a product on the basis of a picture later recalled information about the product's specific attributes that was consistent with this impression rather than inconsistent with it.

A quite different demonstration of the impact of goal-directed processing on selective attention to information was provided by Ross, Lepper, Strack, and Steinmetz (1971). Participants read a clinical case study with instructions to explain either why the protagonist might have committed suicide after leaving therapy or, alternatively, why he might have donated a large sum of money to the Peace Corps. Later, they were asked to predict the likelihood that the protagonist engaged in a number of activities, including the one they had considered earlier. Participants were given convincing evidence that neither the experimenter nor anyone else actually knew what had happened to the protagonist after leaving therapy. Nevertheless, they predicted the outcome they had explained to be more likely than the outcomes they had not explained. Participants in generating their explanation selectively attended to features that were consistent with this explanation. Later, they used this selective subset of features as a basis for their prediction to the exclusion of other information that had been presented.

The Impact of Affect on Selective Attention

When people's processing objectives do not bias the information to which they attend, goal-irrelevant factors may have an impact. One such factor may be the affective reactions that people happen to be experiencing at the time the information is received. A study by Bower, Gilligan, and Monteiro (1981) is illustrative. Participants under hypnosis were instructed to recall a past experience that made them feel either happy or sad and then to maintain these feelings after they were brought out of their hypnotic state. Then they read a passage about two persons that described both happy events and unhappy events that occurred to them. Finally, they recalled the information they had read. Participants who had been induced to feel happy recalled a greater proportion of positively-valenced events, and a lower proportion of negatively-valenced events, than did participants who were induced to feel sad. It is unclear whether these effects were due to the affect that participants were experiencing per se or to the semantic concepts that were activated in the course of inducing these feelings (e.g., Niedenthal & Setterlund, 1994; Niedenthal, Halberstadt, & Setterlund, 1997; Wyer, Clore, & Isbell, 1999). Be that as it may, the study provides strong evidence that concepts activated by experiences of which participants were not consciously aware can bias the information they later identify and encode into memory.

In a study of greater relevance to consumer judgment (Adaval, 2001), participants who had been induced to feel happy or unhappy were later asked to judge an article of clothing that was described by an attribute that was either likely to be evaluated on the basis of subjective criteria (e.g., how it felt to wear it) or not. Participants weighted attributes more heavily in making their judgments if the affect they elicited was similar to the affect they were experiencing than if it was not. Thus, as in Bower et al.'s (1978) study, participants appeared to give more attention to information that was affectively congruent with the feelings they were experiencing for other, unrelated reasons, and so this information had more impact on the judgments they reported later.

The aforementioned studies converge on the conclusion that people with a specific subset of concepts accessible in memory (either because of a goal they are pursuing or for other, unrelated reasons) often give greater attention to aspects of information that can be easily encoded in terms of these concepts, and so the information has greater impact on judgments and decisions than it otherwise would. Selective attention to information that can be interpreted along an accessible dimension could occur as well. Evidence that persons interpret individual product attributes along dimensions that happen to be accessible in memory was obtained by Park, Yoon, Kim, and Wyer (2001) in a study to be described in more detail presently.

Categorical vs. Piecemeal Information Processing

The impact of affect on selective attention can result from other processes as well. Bless (2001) suggests that people who experience positive affect tend to use broader, categorical criteria for judgment than others do. This could result from a more general disposition to perceive the world as unproblematic and, therefore, to believe it is unnecessary to consider information in detail in order to make a judgment (Schwarz & Clore, 1990). In the consumer domain, this suggests a tendency for persons who experience positive affect to give more weight to global judgmental criteria (e.g., brand name, country of origin, etc.) than to specific attribute information. However, although this appears to be true, it is not for the reason that Schwarz and Clore's (1990) conceptualization suggests. Tesser (1978) suggests that people tend to evaluate a stimulus more extremely after thinking about it more extensively. If this is so, and if positive affect increases the attention to categorical bases for judgment, people may think about this information more extensively at the time it is presented and, therefore, may perceive its implications to be more extreme. This shift in the interpretation of the information could lead it to have greater impact independently of the weight attached to it at the time of judgment.

Adaval (2003) confirmed this possibility. She employed procedures developed by Anderson (1971, 1981) to distinguish between the scale values assigned to individual pieces of information (an indication of their evaluative implications) and the weight attached to them at the time of judgment. Inducing participants to experience positive affect at the time they received product information increased the extremity of the evaluative implications they attached to brand name without affecting the weight they attached to it. (That is, they evaluated favorable brands more favorably, and unfavorable brands more unfavorably, than control subjects did.) Moreover, once this interpretation was made, its impact persisted over time, as implied by Principle 3. Thus, participants who had received information about a product's brand name were asked 24 hours later to indicate their preference for this product and another that was normatively similar to it favorableness. Participants who had been happy at the time they considered the first product preferred it to the second product if the products' brand names were both normatively favorable. However, they preferred the second product to the first if the products' brand names were both unfavorable.

THE INTERPRETATION OF AMBIGUOUS INFORMATION

Several examples of the effect of attribute concept accessibility on the interpretation of ambiguous information were provided in our general discussion of knowledge accessibility earlier in this chapter (cf. Bargh & Pietromonaco, 1982; Higgins et al., 1977; Srull & Wyer, 1979) and do not need to be reiterated. However, some additional considerations warrant further consideration.

DIMENSIONAL VS. CATEGORY ACCESSIBILITY

Information can be ambiguous in terms of both the attribute dimension to which it pertains and the value it implies along this dimension (Higgins & Brendl, 1995). The attribute information “50% more banana flavoring,” for example, has implications for both taste and healthfulness. Along a dimension of taste, however, it could be interpreted either favorably (as sweet) or unfavorably (as *too* sweet). The dimension along which the attribute description is interpreted may depend on whether health-related or taste-related concepts are more accessible in memory at the time.

An additional consideration arises, however. People are likely to interpret the aforementioned product description more favorably if concepts associated with good taste have been primed than if concepts associated with bad taste have been primed. However, the attribute’s implications along a dimension of healthfulness are unambiguously negative. In this case, what effect does priming “healthy” have, as opposed to priming “unhealthy?”

Many bipolar attribute concepts (“bad” vs. “good,” “hot” vs. “cold, etc.) may be strongly associated in memory (Colombo & Williams, 1990). To this extent, priming one of these concepts may activate the second as well. In the present example, “healthy” and “unhealthy” might be strongly associated. If this is so, priming *both* concepts might increase the tendency to interpret the attribute described by “50% more banana flavoring” as unhealthy.

Park et al. (2001, Experiment 2) showed this to be true. Participants received materials that activated concepts associated with good taste, bad taste, good health, or bad health. Then, as part of an ostensibly unrelated experiment, they received an ad that contained a description of a milk product similar to that in the preceding example. That is, it had ambiguous implication for taste but clearly implied that the product was unhealthy. After seeing the ad, participants first generated an open-ended description of the product and then evaluated it. Participants who had been primed with a taste-related concept were more likely to describe the product in terms of this concept rather than its bipolar opposite. In contrast, participants who had been primed with a health-related concept were likely to describe the product as unhealthy regardless of whether good health or bad health was primed. Furthermore, their overall evaluations of the product were affected in the manner suggested by their open-ended attribute descriptions.

ASSIMILATION AND CONTRAST

Park et al.’s (2001) study provides an example of conditions in which activating a concept can have a contrast effect on the interpretation of information. (That is, priming “healthy” led participants to judge the product as more unhealthy, and to evaluate it more unfavorably, than they otherwise would.) However, contrast effects can also occur for other reasons. Herr (1986), for example, exposed participants to names of either moderately hostile individuals (e.g., Mohammed Ali) or extremely hostile persons (e.g., Adolf Hitler) before they evaluated a person whose behaviors were ambiguous with respect to hostility. Although priming moderately hostile exemplars had a positive

impact on participants' judgments of the target's hostility, priming extremely hostile exemplars had a contrast effect.

There are two interpretations of these findings. First, when the implications of a concept are so extreme that the concept cannot be applied to stimulus information, it may be used as a standard of comparison. As a result, the stimulus might be assigned a lower value along the dimension of judgment than it would if the standard were more moderate. Second, standards of comparison are more likely to be used when the priming stimuli are people or objects of the same type as the target rather than general attribute concepts of the sort that were primed in the studies by Higgins and others (Moskowitz & Skurnik, 1999; Stapel & Koomen, 1997). In Herr's study, participants may have interpreted the target's behavior in terms of the attribute concepts activated by the priming stimuli in all conditions, regardless of the extremity of these stimuli. Once this interpretation was made, however, they may have spontaneously compared the target to the type of persons described in the priming task, and this effect may have overridden the effect of the primed concepts on the interpretation of the information at an earlier stage of processing.

DESCRIPTIVE VS. EVALUATIVE ENCODING

The criteria that people bring to bear on the interpretation of information can be either descriptive or evaluative. Thus, "stole a magazine from the newsstand" could be interpreted either as "dishonest" or, more generally, as "bad." Similarly, "60 miles per gallon," could be interpreted as either "fuel efficient" or "desirable." Normally, the concepts that are accessible at the time information is first interpreted are likely to influence evaluations only if they are descriptively applicable. In the aforementioned study by Higgins et al. (1977), for example, priming trait concepts such as adventurous or reckless affected the interpretation of information that a person wanted to cross the Atlantic in a sailboat, but priming evaluatively toned but descriptively inapplicable concepts ("kind," "hostile," etc.) did not.

There are two qualifications on this conclusion, however.

1. Once information about a stimulus is interpreted in terms of concepts that are accessible at the time, the stimulus may be attributed the characteristic implied by the interpretation. Once this occurs, the stimulus may be inferred to have other characteristics that are descriptively irrelevant to the primed concept but have become associated with this type of stimulus through learning. Thus, for example, priming a concept of hostility could affect the interpretation of a target person's behaviors that were ambiguous with respect to this particular attribute. If the target is inferred to be a "hostile person" on the basis of this interpretation, he may then be attributed other characteristics that have nothing to do with hostility per se but are stereotypically associated with individuals who possess this attribute (Srull & Wyer, 1979, 1980).
2. Traits with extreme evaluative implications may be spontaneously associated with a concept that summarizes these implications through learning. In these circumstances, priming the trait concept may spontaneously activate the evaluative concept that is associated with it as well. Thus, for example, "malevolent" may activate a negative evaluative concept ("bad"). The latter concept, once activated, could then influence the interpretation of information that is ambiguous with respect to other attributes that have evaluative implications (Stapel & Koomen, 2000).

GOAL-ACTIVATED PRIMING EFFECTS

To reiterate, people's goals at the time they receive information can activate concepts that are relevant to these goals. These concepts may influence not only which information they encode into memory, as noted in the preceding section (Snyder & Cantor, 1979) but also the interpretation of information to which the concepts apply. A study by Higgins and Rholes (1978) exemplifies these effects. Participants who had read a passage about a target person that was ambiguous with respect to the traits it implied were told to describe the person to another who either liked or disliked him. They communicated their description in terms that were evaluatively consistent with the attitude of the individual to whom they were communicating. As a consequence, both their own liking for the person and their memory for the original information were biased toward the implications of the communication they had prepared. This bias was not evident when participants anticipated writing a communication about the person but did not actually do so. Thus, their interpretation of the information in terms of goal-activated concepts was not spontaneous, but occurred only in the course of generating a goal-relevant message. Once this interpretation was made, however, it affected participants' own impression and evaluation of the target person, as implied by Principle 3.

It is interesting to speculate about the implications of these results for consumer judgments and decisions. For example, word-of-mouth communications about a product are often tailored to fit the expectations of the person to whom one is communicating (Grice, 1975; see also Higgins, 1981; Schwarz, 1994; Strack, 1994). As a result, they are likely to influence communicators' own interpretation of the information being transmitted and, perhaps, their evaluations of the product they are describing. For similar reasons, sales persons' own evaluations of the products may be influenced in a direction that is consistent with the communication they generate when extolling the product's virtues to their customers. (The tendency for people to change their attitudes to conform to implications of the communications they have generated is also predicted by cognitive dissonance theory, of course; see Festinger, 1957.) At the same time, the objective of selling the product is not sufficient to induce this change; the sales persons must actually deliver the communication for their underlying evaluations to be affected.

HIGHER ORDER COMPREHENSION PROCESSES

The preceding research focused on the effect of single concepts on the interpretation of single pieces of information. However, more complex bodies of knowledge can often influence the interpretation of new information. This knowledge might be chronically accessible as a result of its frequent use in the social environment in which one participates on a daily basis. On the other hand, situation-specific features that are contained in this knowledge could also activate it. Research in many areas exemplifies this possibility.

Chronic Accessibility of Knowledge

In an early study by Anderson, Reynolds, Schallert, and Goetz (1977), music education majors and physical education majors read a passage about a social interaction that could be interpreted as either a card game or the rehearsal of a woodwind ensemble (e.g., "...they couldn't decide exactly what to play. Jerry eventually took a stand and set things up...Karen's recorder filled the room with soft and pleasant music...finally, Mike said, 'Let's hear the score'...They listened carefully and commented on their performance.") After reading the passage, participants were asked what the

protagonists had commented on. Responses indicated that music majors were significantly more likely to interpret the interaction as a music rehearsal than physical education majors were. Correspondingly, physical education majors were more likely than music education majors to interpret a second ambiguous passage as the description of a wrestling match rather than a jail break. Apparently, concepts that were chronically accessible as a result of their vocational and educational goals affected their interpretation of the story and, therefore, their responses to questions about it.

The knowledge that is necessary to comprehend information can often be called to mind by a single word or phrase. In a study by Bransford, Barclay, and Franks (1972), participants were asked to learn sentences such as “The haystack was important because the cloth would rip,” “The notes were sour because the seam was split,” etc. Their memory for these ostensibly anomalous sentences was typically very poor. However, participants’ memory improved substantially when the sentences were preceded by with a single word (“parachute” and “bagpipes,” in the preceding examples). The word apparently stimulated the activation of a complex body of knowledge that permitted participants to construct a mental representation of the situation described by the sentence that followed it, thus giving the sentence meaning and facilitating memory for it. In other research (Bransford & Johnson, 1972; Bransford & Stein, 1984), paragraphs containing a series of ostensibly unrelated sentences were given meaning, and therefore remembered better, by providing a title that allowed the sentences to be conceptually integrated.

Framing Effects

The importance of Bransford’s work lies in its implication that simple words and phrases can prime quite diverse bodies of knowledge for use in interpreting information and construing its implications. These effects can be reflected in not only memory but also judgments. This is evidenced by Tversky and Kahneman’s (1982; Kahneman & Tversky, 1982) research on decisions under uncertainty. To give a well-known example, imagine that 1,000 people are in danger of being infected with a deadly virus, that one serum, A, is definitely effective but in short supply, and that a second, B, is available to all but of uncertain effectiveness. Consider two possibilities:

1. If serum A is administered, 350 people will be saved. If serum B is administered, there is a 65% chance that everyone will be saved but a 35% chance that no one will be saved.
2. If serum A is administered, 650 people will die. If serum B is administered, there is a 35% chance that everyone will die but a 65% chance that no one will die.

Although the choice alternatives are identical, people are more likely to choose serum A in the first case, but serum B in the second. Presumably the first set of alternatives stimulates people to think about living, and so people choose the alternative that guarantees this positive outcome. However, the second set stimulates people to think about dying, and so they choose the alternative that has a chance of avoiding this negative fate.

MEMORY PROCESSES

The factors that influence the effect of knowledge accessibility on comprehension and judgment obviously exert this influence through their mediating effect on the concepts and cognitions that people retrieve from memory. In this section, we will restrict our discussion to research in which memory is the primary concern, independently of the effects that the remembered information has on judgments or decisions. In doing so, we focus on two memory phenomena: (1) the role of

implicit theories on constructive and reconstructive memory, and (2) the interference of accessible knowledge representations on memory for the information on which these representations were based.

THE ROLE OF IMPLICIT THEORIES ON RECONSTRUCTIVE MEMORY

People may not pay equal attention to all details of an experience at the time it occurs. Moreover, unless the experience is particularly noteworthy, it may get “buried” among the large number of other experiences that people have in their daily lives. This is particularly true when the events that compose the experiences are rather commonplace. In many cases, people may interpret these experiences in terms of an implicit theory they have acquired about the type of events that occurred. If such a theory is frequently used, it may become more accessible in memory than the experiences that it is used to interpret (Principle 2). Consequently, if people are called upon to remember the experience, they may reconstruct it on the basis of this theory without searching memory for a representation of the experience itself.

Studies by Michael Ross (1989) support this contention. For example, women’s recall of their mood swings during their most recent menstrual cycle were more highly correlated with their implicit theories of how they typically felt during their menstrual period than with the feelings they had actually reported at the time. In a second study (Conway & Ross, 1984), participants who received feedback about the results of a study skills training program recalled their pre-training ability to be lower if they believed that the training was effective than if they did not, independently of their actual improvement over the training period.

The role of implicit theories in memory is also suggested in a study by Bem and McConnell (1972). Participants whose attitudes toward a position had been assessed in an earlier experimental session were either asked to generate a counter-attitudinal communication voluntarily or told to do it without being given a choice. After generating their message, they were asked to recall the attitude they had reported in the earlier session. Participants recalled having more favorable attitudes toward the position advocated when they had generated the communication voluntarily than when they had not been given a choice. Participants apparently used their most recent behavior as a basis for inferring what their attitude must have been, based on an implicit theory that people who advocate a position voluntarily are likely to advocate it personally, without consulting their memory for the actual attitude they had reported.

INTERFERENCE OF ACCESSIBLE KNOWLEDGE ON MEMORY

According to Principle 3, mental representations that have been formed from information are typically more accessible in memory than the information on which they are based. Therefore, they tend to be used as a basis for reconstructing this information without recourse to the original material. In some cases, this can lead to memory errors. Schooler and Engstler-Schooler (1990) showed that people are less able to identify a face they have seen if they had described the face verbally at the time they first encountered it than if they had not. Adaval and Wyer (2004) obtained analogous effects in a situation more closely approximating those that occur outside the laboratory. Specifically, participants who had seen a movie about an interaction between a married couple were asked either to describe the sequence of events they had seen or to describe their impressions of the protagonists. Both writing tasks decreased participants’ later recognition of things the protagonists had said during the interaction. Furthermore, describing the events that occurred decreased recognition of nonverbal behaviors as well. In this research, as in Schooler’s, the mental

representations that participants constructed in the course of writing the description, which were more abstract than the visual representation that they formed of the stimulus information at the time they encountered it, were later used as a basis for their recognition responses instead of this representation. Consequently, recognition accuracy decreased.

The representations that people construct as a result of post-information processing can not only interfere with the events they actually observe but also can produce intrusions. A classic study by Loftus and Palmer (1974) showed that asking participants questions about a traffic accident they had seen in a picture (e.g., “How fast was the car going when it smashed into the tree?”) led them to reconstruct a memory of the accident in the course of generating an answer that contained features that they had not actually seen but were consistent with the implications of the question. Consequently, their later use of this reconstructed representation as a basis for recalling the picture’s content produces intrusion errors. Other studies demonstrate the implications of reconstructive processes for the reliability of both “eye-witness” testimony (Loftus, 1975) and early childhood memories (Loftus, 2000).

Although the preceding examples pertain to the interference effects of recently constructed representations, recently *used* representations can have similar effects. Perhaps the best known examples of this influence are the part-list cueing effects identified by Slamecka (1968; Rundus, 1973). That is, when participants who have learned a series of stimulus items are given a subset of these items to use as retrieval cues, their memory for the remaining items in the list decreases. In a quite different paradigm, Macrae et al. (1995) found that when participants have been exposed to an Asian woman, they are subliminally primed with concepts pertaining to one of the two stereotypes that could be used to describe the person, the accessibility of concepts related to the other, unprimed stereotype (as inferred from response times in a lexical decision task) decreased.

Although the specific phenomena summarized in this section are somewhat remote from consumer behavior, their potential implications are nonetheless fairly clear. For example, people who have communicated about a product to others may not only choose to evaluate the product in a manner that is consistent with the communication they have generated as suggested in the previous section, but their memory for their actual experience with the product may be influenced correspondingly. Furthermore, their implicit theories about the quality of a product or service provider, if easily accessible in memory, could also bias their memory for their past experience independently of their actual reactions to the product or service at the time the experience occurred (Ross, 1989).

INFERENCE AND EVALUATION PROCESSES

Inferences are of many types. For example, people often infer the *likelihood* that a product has a certain attribute, that a statement is true, that an event will or did occur, or that a decision will have certain consequences. Second, they may estimate the *magnitude* of an attribute (the age of a bottle of wine, the price of a cashmere sweater). Third, they may *evaluate* a product as good or bad, or may have a *preference* for one alternative over another. In each case, however, the inference is unlikely to be based on an extensive analysis of all of the knowledge one has acquired that might be relevant, or a exhaustive construal of its implications (Principle 1). Rather, it is based on only a subset of relevant knowledge that happens to come to mind most easily. A complete discussion of these possibilities would far exceed the scope of this chapter. We therefore restrict our discussion to a few representative examples.

BELIEF ESTIMATION

Probability estimates can usually be viewed as *beliefs*. They can pertain to the occurrence of a past or future event (e.g., that Saddam Hussein had a stockpile of nuclear weapons, the United States will go to war with China before the end of the decade), or to the existence of a present state of affairs (e.g., Texas is bigger than Alaska, George W. Bush will receive the Nobel Peace Prize). Or, they could concern the causal relation between two events or states. More generally, beliefs are estimates of the likelihood that a proposition about an event, state or relation is true.

People who are asked their belief in a proposition may often search memory for previously acquired knowledge that bears on it. In some cases, this knowledge could itself be a semantically-coded proposition whose features are very similar to those of the proposition being evaluated. Alternatively, people may identify a second proposition that, if true, has implications for its validity. Finally, it could be an implicit theory that has implications for the validity of the proposition being judged.

A theory of comprehension by Wyer and Radvansky (1998; see Wyer, 2004) formalizes the first possibility. They assumed that to comprehend a piece of information, people form a mental representation of its features and search memory for a previously formed representation that contains these features. If similarity of the features of the new representation to those of an existing memorial representation is very high, people not only comprehend it but spontaneously identify it as true.

One implication of this conceptualization is that past experiences that lead a statement to be represented and stored in memory will increase the likelihood that people consider the statement to be true if they encounter it at a later point in time (Begg, Anus, & Farinacci, 1992). In a study by Hasher, Goldstein, and Toppin (1977; see also Hawkins & Hoch, 1992; Kelley & Lindsey, 1993), people completed a belief questionnaire in two different experimental sessions. Some items in the first questionnaire, which concerned obscure facts that few if any participants were likely to know, were repeated in the second. Participants typically judged these propositions as more likely to be true in the second session than they had initially. Exposure to the items in the first session apparently led them to seem more familiar in the second session, and so participants' belief in their validity increased. In a conceptually similar study, Jacoby, Kelley, Brown, and Jasechko (1989) found that exposing participants to fictitious names during an initial experimental session increased participants' beliefs that the names referred to well-known persons when they encountered the names 24 hours later.

These effects occur in part because the information to which people are exposed becomes dissociated from its source. If this is so, the information could have an effect on beliefs even when it is identified as invalid at the time it is first received. This possibility was demonstrated by Skurnik, Yoon, Park, and Schwarz (in press). Participants were exposed to statements about commercial products either one, two, or three times, in each case accompanied by an indication that the statement was not true. Participants, a short time after exposure to the statements, were less likely to believe the statements were true if they had been exposed to them three times than if they had been exposed to them only once. After a 3-day delay, however, older participants were *more* likely to believe the statements in the former case. (This was not true of college-age participants, suggesting that these subjects were less likely to dissociate the statements from their initial context than older subjects were.)

When a previously formed representation of a proposition does not easily come to mind, people are likely to search for other information that bears on its validity. (McGuire & McGuire, 1991).

Based on an earlier formulation of belief organization by McGuire (1960), Wyer and Hartwick (1980) proposed a conceptualization of conditional inference processes that recognize this possibility. That is, people who are asked to report their belief in a conclusion, *C*, search memory for an antecedent, *A*, that has implications for it, and estimate the likelihood that *C* would be true if *A* is or is not true. If these conditional beliefs differ, they average their implications, weighting each by their belief that *A* is and is not true, respectively. If the beliefs are in units of probability, this inference can be captured by the equation:

$$P(C) = P(A)P(C/A) + P(\sim A)P(C/\sim A), \quad [1]$$

where $P(C)$ is the belief that *C* is true, $P(A)$ and $P(\sim A)$ are beliefs that *A* is and is not true, respectively, and $P(C/A)$ and $P(C/\sim A)$ are conditional beliefs that *C* is true if *A* is and is not true, respectively. If $P(\sim A) = 1 - P(A)$, the effect of a communication changes beliefs in *A* by the amount $\Delta P(A)$ should theoretically induce a change in beliefs in *C*, $\Delta P(C)$, that is predictable from the equation:

$$\Delta P(C) = \Delta P(A)[P(C/A) - P(C/\sim A)]. \quad [2]$$

The difference between the two conditional beliefs is essentially an estimate of the perceived relevance of beliefs in *A* to beliefs in *C*.

The relevance of this conceptualization in the present context derives from its implication that people who estimate their belief in a proposition do not conduct an exhaustive search of memory for knowledge that has implications for its validity. Rather, they identify and use the first relevant "informational" proposition (*A*) that comes to mind. Therefore, when more than one such proposition exists in memory, the one that is most quickly and easily accessible is used. To give a specific example, the belief that drinking coffee is desirable (*C*) should be stronger if the proposition "Drinking coffee makes you alert" happens to be accessible in memory than if "Coffee gives you insomnia" is more accessible. Equation 1 can be a diagnostic tool for determining whether a particular proposition is used as a basis for beliefs in any given instance. That is, the equation should describe the relations among a set of beliefs associated with propositions *A* and *C* if *A* has been used as a basis for reporting beliefs in *C* than if it has not (Wyer, 1970; Wyer & Hartwick, 1980, 1984).

The effectiveness of advertisements could potentially be diagnosed in terms of this conceptualization. Suppose a commercial that asserts "Brand X has more energizing ingredients" (*A*) fails to change consumers' beliefs that they would purchase this product; that is, $\Delta P(C) = 0$, as defined in Equation 2. This could occur for three reasons. First, the commercial might have been ineffective in changing beliefs that *X* has more energizing ingredients; that is, $\Delta P(A) = 0$. Second, consumers' beliefs about *X*'s energizing ingredients might be irrelevant to their belief that they would buy it, or $P(C/A) = P(C/\sim A)$. Finally, the commercial might be effective in changing consumers' belief about the product, $P(A)$, and this belief might potentially be relevant. However, consumers might have typically think about other judgmental criteria than *A* at the time they report their purchase intentions, as reflected in a discrepancy between obtained and predicted values of $\Delta P(C)$.

The third possibility raises an additional implication of the model that was initially proposed by McGuire (1960) and confirmed empirically by Rosen and Wyer (1972). That is, syllogistically related beliefs may sometimes be inconsistent because they have not recently been thought about in relation to one another. However, asking people to report these beliefs in temporal proximity may call attention to their inconsistency and, therefore, may stimulate attempts to eliminate it. As a result, the beliefs may become more consistent if they are reported again at a later point in time. This "Socratic" effect was demonstrated in consumer research by Kardes, Cronley, Pontes, and Houghton (2001), who also applied the model in diagnosing the influence of multiple sets of syllogistically related arguments and their impact on resistance to persuasion.

FREQUENCY ESTIMATION

Frequency estimates are conceptually related to probability estimates; the higher the frequency of an event's occurrence, the more likely it is. Nevertheless, the processes that underlie these two types of estimates can differ. The different strategies that people use to compute the incidence of an event, and the conditions in which they are applied, have been investigated by Menon (1993; Menon, Raghubir, & Schwarz, 1995). When an event occurs regularly (as in eating breakfast, or tooth-brushing), for example, people are likely to estimate its incidence within a given time period by simply extrapolating, based on general knowledge of its frequency of occurrence over the course of a day or week. When an event occurs irregularly, however, people are more likely to search memory for specific instances of the event or attribute being judged. As implied by Principle 1, however, this search is unlikely to be exhaustive. Rather, people may base their judgment on how easily these instances come to mind.

This tendency, which was referred to by Tversky and Kahneman (1973) as the *availability heuristic*, may be a manifestation of a more general tendency to treat conditional rules of inference as biconditionals (Wyer & Srull, 1989). Thus, because people believe that things that occur frequently are likely to come to mind easily, they infer that things that come to mind easily are likely to occur frequently. As a result, objectively irrelevant factors that influence the accessibility of instances in memory can have an impact on frequency estimates.

One such factor, noted earlier, is simply the amount of thought that was devoted to these instances at the time they were first encountered. That is, the incidence of events and attributes that stimulate attention at the time they are encountered is likely to be overestimated. Hamilton and Gifford (1976), for example, found that people were more likely to overestimate the proportion of minority representatives in a fictitious group when the group was small in size (and, therefore, the number of minority members observed was correspondingly small) than when it was large.

A qualification on this conclusion was identified by Briley, Shrum, and Wyer (2006) in a study more directly relevant to consumer behavior. European Americans and African Americans were shown a series of clothing ads in which the number of Black (vs. White) models in the ads was systematically varied while holding the relative proportion of these models constant. Later, they were asked to estimate the number of models of each ethnicity that were contained in the ads and were also given a test of recognition memory for the specific models they had seen. European Americans overestimated the incidence of Black models when the frequency of their occurrence was low, but their accuracy increased as the number of models presented became larger. These participants apparently paid relatively more attention to the individual Black models at the time they were presented (as evidenced by the accuracy with which these models could later be recognized), and later used the ease of retrieving the models from memory as a basis for their frequency estimates. In contrast, African Americans, who had a personal interest in ensuring that their ethnic group was represented adequately, appeared to conduct an online count of the models at the time the models were encountered without paying attention to their individual features. Consequently, their ability to recognize the specific models presented was low. Nevertheless, their frequency estimates were quite accurate when only a few models were presented, but became less so as the number presented increased and were more difficult to keep track of.

Perceptions of Social Reality

When people are unmotivated to think extensively about the objects and events they encounter, an additional consideration arises. That is, people who simply comprehend information with no

particular objective in mind may simply store the information in memory without attending to the context in which they encountered it. This information may later be retrieved out of context and used as a basis for judgment.

Shrum (2000) and his colleagues provide abundant evidence of this in research on the effects of watching television on perceptions of social reality. That is, people typically overestimate the incidence of objects and events in the real world when these entities occur frequently on television. Furthermore, the amount of this overestimation increases with the amount of television that people watch. Thus, heavy television viewers are more likely than light viewers to overestimate the incidence of crime, the numbers of lawyers and doctors, and the number of people who have swimming pools in their back yard (O'Guinn & Shrum, 1997). This "cultivation effect" (Gerbner, Gross, Morgan, & Signorielli, 1994) occurs independently of the educational and socioeconomic level of respondents. Rather, heavy television viewers are more likely to have instances of these stimuli easily accessible in memory and, therefore, estimate them to occur more frequently in the real world than light viewers do (O'Guinn & Shrum, 1997; Shrum, Wyer, & O'Guinn, 1998).

Additional Considerations

The ease of retrieving instances of an object or event should be distinguished from the actual number of instances that are retrieved. In fact, the effects of these variables can be opposite in direction. This possibility has been demonstrated in a number of innovative studies by Schwarz and his colleagues (for a review, see Schwarz, 1998, 2004). In one study, for example (Schwarz et al., 1991), people were asked to recall either 6 instances of assertive behavior or 12 such instances. Although 12 behaviors are likely to imply greater assertiveness than only six, participants judged themselves to be *less* assertive in the former condition than the latter. That is, participants who were asked to recall 12 assertive behaviors found it very difficult to do so. Consequently, they inferred that they actually did not have the attribute in question. Similar effects have been identified in other domains. For example, people who were asked to generate seven arguments in support of a position tended to report less favorable attitudes toward the position than those who were asked to generate only three (Wänke, Bless, & Biller, 1996), and individuals who generate many reasons why an event might not occur are more likely to believe that it did occur than are individuals who generate few such reasons (Sanna & Schwarz, 2003; Sanna, Schwarz, & Stocker, 2002).

Similar effects have been found in the consumer domain. For example, people report less favorable attitudes toward commercial products (e.g., a BMW) if they have listed many reasons for using the products than if they have listed only one (Wänke, Bohner, & Jurkowitsch, 1997). In a similar study, participants judged a computer they had seen advertised more favorably after being asked to recall two favorable features of the computer than after being asked to recall eight (Menon & Raghuram, 2003). Interestingly, this difference was reversed under conditions in which subjects were likely to attribute the ease of recalling these features to other, extraneous situational factors (i.e., distracting music).

MAGNITUDE ESTIMATES

People are often called upon to make judgments of magnitude. They might estimate the height of a mountain, the age of an antique, or the price of a product. These estimates are likely to be made with reference to a previously acquired body of knowledge about the type of stimulus being judged. The way in which this knowledge is used can depend on whether the estimate is in physical units (feet, years, dollars, etc.) or subjective ones (high or low, old or young, expensive or cheap, etc.). In

each case, however, the estimate can depend on the particular subset of judgment-relevant knowledge that happens to be accessible at the time.

Estimates in Physical Stimulus Units

Consumers who consider the purchase of a particular product are likely to compare its features to those of other products they have encountered in the past. For example, they may evaluate a car's fuel efficiency in relation to the average miles per gallon of other automobiles they have seen. Or, the price they are willing to pay for the car could require an estimate of the price at which the product is typically available elsewhere. However, people may rarely have these quantities stored in memory, and consequently may consider a range of values to be plausible. This range may depend on the particular subset of past experiences that they use to compute it.

Strack and Mussweiler (1997) formalize this process and provide compelling evidence of its occurrence (Mussweiler & Strack, 1999, 2000a, 2000b; for a review, see Mussweiler, 2003). In their research, participants are typically asked to decide if a stimulus attribute is greater or less than either a high value (e.g., is the price of the average BMW greater or less than \$100,000) or a very low one (\$3,000). Having done so, they then make their own estimate of its value. In making their comparative judgment, participants theoretically activate concepts about a subset of stimuli whose values are close to the "anchor" value they are asked to consider. Then, they use these concepts to estimate the actual value when they are asked to report it later. Thus, in our example, participants estimate the average price of a BMW to be higher if they have been asked to compare this price to a higher value than if they have been asked to compare it to a lower value. This is true even when this value is implausible. In fact, it even occurs when participants believe that the "anchor" value was chosen at random and was objectively irrelevant to the stimulus being judged (Strack & Mussweiler, 1997).

Adaval and Wyer (2005) found that exposing participants to a high or low anchor price can affect their estimates of not only the average price of a product in the marketplace but also the price they are personally willing to pay for it. Nunes and Boatwright (2004) reported conceptually similar effects in field research and showed that the effects can generalize over product domains. For example, passersby at a beachfront stand were willing to pay more money for a CD if the sweaters displayed at a nearby stand were on sale for a high price than if they were on sale for a low price.

This result should not be overgeneralized, however. Adaval and Wyer (2005) found that the impact of context prices on estimates of prices of products in other categories depends on the relevance of the thoughts activated by the comparative judgment task. Thus, making comparative judgments of clothing articles stimulated participants to think about the subjective reactions they might have to the use of these articles and to the shopping experience itself. Consequently, it influenced the price they were willing to pay for electronic products to which the (e.g., affect-related) concepts activated by these thoughts were also relevant. However, making comparative judgments of an electronic product stimulated participants to think about features that were specific to the type of product being judged. Consequently, it had little impact on the price they were willing to pay for clothing articles.

Subjective Magnitude Estimates

As the preceding considerations suggest, people frequently fail to remember the specific physical characteristics of a stimulus. (Consumers, for example, are unable to remember the price of a product they have purchased only seconds after they put in their shopping cart; see Dickson &

Sawyer, 1990.) Rather, they encode an object's physical units into subjective units at the time they encounter them and this encoding, once stored in memory, is later retrieved and used as a basis for later judgments and decisions.

The rules for transforming physical stimulus values into subjective values were described by Ostrom and Upshaw (1968; see also Parducci, 1965), and have been explicated in consumer research by Janiszewski and Lichtenstein (1999) and Lynch, Chakravarti, and Mitra (1991). According to Ostrom and Upshaw, people subjectively position the range of subjective values they have available to correspond to the range of physical stimulus values they consider to be relevant. Thus, the higher the range of physical stimulus values they consider, the lower the subjective value they assign to any given stimulus within this range. In some instances, the range of physical values they consider is determined by the type of stimuli being judged. For example, people might judge a baby as "big" but an apartment as "small" although few babies are as large as apartments. When the range of values that are relevant to a judgment are less clear, however, it may depend on the subset of physical stimulus values that happen to be accessible in memory at the time. Consequently, it may be influenced by factors of which they are unaware, and that are objectively irrelevant to the judgment to be made.

Adaval and Monroe (2002) confirmed this possibility. Participants were subliminally exposed to either high or low numbers in the course of performing an ostensibly unrelated perceptual task, and then were asked to judge a particular product on the basis of price and attribute information. Participants judged the product to be less expensive if they had been exposed to high numbers than if they had been exposed to low ones. Interestingly, they judged the product to be lower along other dimensions as well. Apparently, exposure to the numbers during the priming task affected the perspective that participants adopted in transforming objective stimulus values into subjective values regardless of the dimension to which the judgments pertained.

In summary, both physical stimulus estimates and subjective judgments can be influenced by the particular subset of knowledge that happens to be accessible at the time the judgments are made. However, the effects of this knowledge on the two types of judgments may be opposite in direction. For example, activating knowledge about high-priced products can increase participants' estimates of the average price of these products in the marketplace and the price they are willing to pay for them. On the other hand, this activated knowledge may also increase the range of values that compose the perspective that participants bring to bear on their subjective estimates to the product's cost. Thus, it may decrease their judgments of the product as expensive.

EVALUATIONS AND AFFECT-BASED JUDGMENTS

Evaluations that are reported along a good-bad dimension are essentially estimates of magnitude. However, they are distinguished from other magnitude estimates in two ways. First, they typically apply to a stimulus as a whole, and may reflect the combined implications of inferences about a number of more specific attributes (for discussions of these integration processes, see Anderson, 1971, 1981; Fishbein & Ajzen, 1975). Second, evaluations of a stimulus are often based on not only its descriptive features but also the affect that people happen to experience and attribute to their feelings about the stimulus. The possible use of affective reactions as bases for judgment, which was initially demonstrated by Schwarz and Clore (1983), is very well established both in consumer research (Pham, 1998, 2004; Yeung & Wyer, 2004, 2005) and more generally (Schwarz & Clore, 1996; Wyer, Clore, & Isbell, 1999).

Not all evaluations are based on affect, of course (Zanna & Rempel, 1988). Some products are typically evaluated on the basis of purely functional or utilitarian criteria. Consumers may consider their feelings to be irrelevant to their evaluation of these products and so the affect they are

experiencing has little informational influence (Adaval, 2001; Pham, 1998, 2004; Yeung & Wyer, 2004). In other instances, both affective and nonaffective criteria may be employed. Then, because affective reactions to a stimulus typically occur spontaneously, without a detailed analysis of its specific features (Lazarus, 1982, 1991; Zajonc, 1980), they are likely to be highly accessible and, therefore, likely to be applied (for an exception, see Levine, Wyer, & Schwarz, 1994). Indeed, they may often be used to the exclusion of other information when people are unable or unmotivated to search for additional judgmental criteria (Schwarz & Clore, 1988; see also Forgas, 1995).

This contingency was demonstrated by Shiv and Fedorikhin (1999). Participants in the study were given a choice of eating either chocolate cake or fruit salad. In the absence of distraction, a large proportion of participants chose the fruit salad. When participants were required to keep a multiple-digit number in mind while making their decision, however, their preferences for the chocolate cake significantly increased. Apparently participants who were able to think about the implications of their decision based their choice on health-related criteria. In the presence of distraction, however, the cognitive deliberation required to make this choice was aborted, and preferences were based on hedonic (i.e., affective) criteria.

Further evidence that affect is more likely to come into play when participants are unable to think critically about their judgments was obtained by Albarracín and Wyer (2001). Participants in this study were first induced to feel either happy or unhappy by writing about a past experience. Then, they were exposed to a persuasive message containing either strong or weak arguments in favor of comprehensive examinations. When participants received the message in the absence of distraction, they based their attitudes toward the exams on the content of the message they received. When they were distracted, however, they based their attitudes on the affect that they were experiencing as a result of the past experience they had recalled, and the effect of the message content significantly decreased. Thus, as in Shiv and Fedorikhin's (1999) research, participants' affective reactions had a greater impact on judgments when other criteria could not easily be applied.

Effects of Extraneous Affect on Evaluations

Albarracín and Wyer's (2001) results exemplify a more general phenomenon. That is, people often cannot easily distinguish between their affective reactions to a stimulus and the feelings they may be experiencing for other, unrelated reasons. Consequently, affect from sources that have nothing to do with the object being judged can have an impact on their evaluation of it. Thus, for example, people who have been thinking about a personal experience shortly before they are called upon to evaluate a product may evaluate the product more favorably if they feel happy as a result of these ruminations than if they feel sad.

Numerous situational factors can obviously influence the accessibility and use of affect as a basis for judgment, including the weather (Schwarz & Clore, 1983), a small gift (Isen, Shalke, Clark, & Karp, 1978), performance on an achievement test (Ottati & Isbell, 1996), and proprioceptive feedback (Strack, Martin, & Stepper, 1988). This research typically assumes that judgments are based on an integration of judgment-relevant criteria at the time the judgment is made. In many instances, however, people are likely to form an initial impression of an object before they receive information about its specific features. Once this initial impression is formed, it can later be recalled and used as a basis for judgment without construing the implications of information received subsequently (Principle 5). In this case, the feelings that people happen to be experiencing at the time their initial impression is formed may influence their impression and, as a result, may affect the judgments and decisions they report later. Furthermore, the impact of their feelings may be evident even after the feelings themselves have dissipated.

These considerations are particularly important in purchasing situations. Consumers often form a general impression of a product from seeing it in a store window or magazine. In such conditions, the affect they happen to be experiencing at the time they form this impression could influence their later evaluation of the product independently of any information about its specific features that they acquire later. Yeung and Wyer (2004) confirmed this possibility experimentally. Participants who saw an affect-eliciting picture of a product before they received information about its specific features formed an initial impression on the basis of this picture, and this impression influenced their later product evaluations independently of the specific attribute information they received later. Furthermore, the affect they were experiencing for unrelated reasons at the time the picture was presented had an impact on judgments through its mediating impact on this initial impression.

For affective reactions to have an impact, however, they must not only be accessible but also be relevant to the judgmental goal one is pursuing. Affective reactions influence product evaluations at the time of judgment only if the product is one that is typically based on hedonic rather than utilitarian criteria (Pham, 1998). Similarly, they influence people's initial impressions only if they are relevant to these impressions. Thus, in Yeung and Wyer's (2004) study, the feelings that participants were experiencing for extraneous reasons influenced their initial impressions only if the picture on which they based these impressions elicited affect; they had no influence when the picture conveyed functional characteristics of the product that were not themselves affect eliciting.

Responses to Affect-Congruent Information

A by-product of the use of affect as information may be its influence on the attention that is paid to the information that elicits this affect and, therefore, the weight that is attached to it in making a judgment. A formal statement of this possibility is provided by Adaval's (2001) affect-confirmation theory. She proposed that when information about a product's specific attributes elicits positive or negative affective reactions, the feelings that consumers are experiencing for other reasons can appear either to confirm or to disconfirm the implications of these reactions, making consumers more or less confident that they have assessed these implications correctly. Consequently, these feelings influence the weight they attach to the attribute information in making a judgment. Consistent with conclusions drawn by Pham (1998), however, this differential weighting only occurs when people consider their affective reactions to be a relevant basis for construing the information's evaluative implications. When the attribute information describes functional rather than hedonic qualities, the affect that people experience has no influence on the weight they attach to it.

A recent study by Förster (2004) is also worth noting in this context. He found that proprioceptive feedback (e.g., nodding or shaking the head) influenced participants' evaluations of a product, but only when the implications of the feedback were congruent with the intrinsic favorableness of the product being judged. That is, head nodding influenced evaluations of favorable products but not unfavorable ones, whereas head shaking affected evaluations of unfavorable products but not favorable ones. To the extent proprioceptive feedback elicits affect that is used as a basis for judgment (e.g., Strack, Martin, & Stepper, 1988), these results are consistent with Adaval's (2001) affect-confirmation theory. Other interpretations of these findings are possible, however, as noted later in this chapter.

Effects of Brand-Elicited Affect

The use of affect as a source of information plays a particularly important role in evaluations of brand extensions. It seems reasonable to suppose that the effect of a favorable brand name on evalu-

ations of its extension is greater when the extension is physically or functionally similar to the parent brand category than when it is not (Aaker & Keller, 1990; Bottomley & Holden, 2001). However, Barone, Miniard, and Romeo (2000) found that stimulating participants to experience positive affect at the time they made similarity judgments led them to judge moderately similar extensions as more similar to the parent brand than they otherwise would and, therefore, more similar to the parent brand in favorableness. However, this effect occurs only when (a) participants estimate similarity before they evaluate the extension (Yeung & Wyer, 2005) and (b) are sufficiently motivated to take parent-extension similarity into account (Barone, 2005). When participants evaluate extensions without judging similarity, the affect they are experiencing has a direct, informational impact on judgments that is not mediated by its influence on similarity perceptions.

PREFERENCE JUDGMENTS

Purchase decisions are often comparative. That is, consumers decide which of several alternative products they prefer. In some cases, these decisions are likely to be determined by computing an overall evaluation of each choice alternative independently and comparing the magnitude of these separate evaluations. This process, however, requires cognitive effort. Consequently, if purchasers have not previously made overall evaluations of the products they are considering, they may resort to different strategies that are easier to apply.

For example, people may often perform a dimension-by-dimension comparison, choosing the product that is superior on the greatest number of dimensions. Or, when this procedure does not lead to a clear solution, they may resort to other, heuristic criteria. For example, suppose a product A is superior to B along one attribute dimension but is inferior to B along a second. Nevertheless, suppose consumers believe that A is superior to a third alternative but B is not. Then, they may consider this to be sufficient justification for choosing A despite the fact that a direct comparison of the products is not diagnostic (Shafir, Simonson, & Tversky, 1993; Simonson, 1989; but see Huber, Payne, & Puto, 1982, for a different interpretation). This criterion may only be applied, however, if independent evaluations of the products have not already been computed. If these evaluations have already been made and are easily accessible in memory at the time the products are compared, participants may base their preferences on these evaluations instead (Park & Kim, 2005).

Research on preference judgments has typically been based on the implicit assumption that these judgments are based primarily on the information that is provided in the experiment about the stimuli being judged. Consequently, the role of knowledge accessibility in these judgments has not been directly examined. Nevertheless, several phenomena identified in research in this area provide examples of its influence.

1. If the products described are encountered successively, people may focus their attention on the last alternative, which they have encountered more recently and is presumably more accessible in memory (Principle 2). Thus, they focus their attention on features of this product that the first does not have, and base their preference on the evaluative implications of these features while ignoring features of the first alternative that the second does not possess. Therefore, suppose both alternatives have unique positive features that are similar in favorableness. Then, people are likely to choose the second product they consider, as it has positive features that the first does not possess. In contrast, suppose the alternatives have unique negative features. In this case, people are likely to choose the first product they encountered, as the second has negative features that the first does not (Houston, Sherman, & Baker, 1989).

2. If two choice alternatives have common features and, therefore, are not diagnostic, consumers may ignore them and concentrate their attention on only those features that are unique to each option. Consequently, these latter features, which are processed more extensively, become more accessible in memory than others (Craik & Lockhart, 1972). Therefore, if consumers are later called upon to evaluate each alternative separately, the unique features are likely to be given relatively more weight than the shared features. Thus, for example, consumers who have compared two options that have unique favorable attributes and common unfavorable ones may mentally cancel the unfavorable attributes and consider only the favorable ones in making their choice. As a result, they should later evaluate both products more favorably than they would if the comparative judgment had not been made. Similarly, persons who compare products with common favorable and unique unfavorable features should later evaluate the products more unfavorably than they would otherwise (Houston & Sherman, 1995). This can even occur when persons are not explicitly asked to make these comparisons (Brunner & Wänke, 2006; but see Wang & Wyer, 2002, for contingencies in the occurrence of these effects).

BEHAVIORAL DECISIONS

Some of the most important demonstrations of the influence of knowledge accessibility have emerged in research on its impact on overt behavior. Persons who have unobtrusively been exposed to stimuli that are associated with aggressiveness (e.g., by waiting for the experiment in an office that contains ROTC equipment) are more likely to administer shocks to a confederate in a learning experiment (Berkowitz & LePage, 1967). Priming hostility-related concepts in a sentence-construction task (Srull & Wyer, 1979) can have similar effects (Carver, Ganellen, Froming, & Chambers, 1983).

A particularly compelling series of studies by Bargh, Chen, and Burrows (1996) provide more direct evidence that semantic concepts can have a direct impact on behavior that is not mediated by their influence on how the object of the behavior is interpreted. In one study, for example, participants were primed with concepts associated with rudeness in the course of performing a sentence construction task. These participants were more likely than control participants to interrupt an experimenter's conversation with a graduate student in order to return the questionnaire they had completed. However, their behavior was apparently not mediated by their interpretation of the experimenter's behavior as impolite; judgments of him were unaffected by the priming task.

In a second study, college-age participants completed a sentence construction task that required the use of concepts associated with the elderly. After leaving the experiment, these participants walked more slowly to the elevator than control subjects did. Finally, Caucasian participants who were subliminally exposed to faces of African Americans in the course of performing a boring perceptual task displayed more nonverbal indications of irritation than control participants upon being asked to perform the task a second time. Using similar priming techniques, Colcombe (reported in Wyer, 2004) found that subliminally priming African American faces decreased performance on a test of mathematics ability while increasing performance in tests of rhythm memory and basketball shooting. Numerous other examples are reviewed by Dijksterhuis, Smith, van Baaren, and Wigboldus (2005).

These effects could reflect the impact of "If [X], then [Y]" productions of the sort mentioned earlier in this chapter. That is, a configuration of stimulus features could, in combination, activate a sequence of behaviors that are performed spontaneously, with little if any cognitive deliberation. The configuration could include not only concepts activated by the situation in which the behavior

occurs but also cognitions that happen to be accessible for other reasons. However, people need not be aware of all of the features of this configuration in order for the production to be activated. This possibility was demonstrated by Chartrand and Bargh (1996). They found that subliminally priming concepts associated with a goal-directed production can activate the production without conscious awareness of the goal to which it was relevant.

Although the evidence that behaviors can be influenced by subliminally primed concepts and cognitions is very clear, the cognitive mechanisms underlying these effects are less so (cf. Dijksterhuis et al., 2005; Janiszewski & van Osselaer, 2005; Strack & Deutsch, 2004). Why does priming a stereotype of the elderly, or of African American faces, influence the behavior of persons who are not themselves members of the stereotyped category? One possible answer is suggested by Prinz (1990), who postulated that in order to comprehend another's behavior, one must mentally simulate the performance of the behavior oneself. This process could establish a direct link between the representation of another's behavior and a representation of one's own, and the product activated by the latter representation, along with features of the situation itself, could elicit this behavior under conditions in which it is appropriate.

Another possibility is that priming a stereotype activates a general value (e.g., that people should not be taken advantage of, that academic achievement is unimportant, etc.) and that these values, once activated, have a mediating influence on people's behavior in the situation at hand. Thus, stimulating people to think about Nobel Prize winners leads them to perform better in a game of Trivial Pursuit (Dijksterhuis & van Knippenburg, 1998), and priming concepts associated with the elderly decreases college students' performance on a memory test (Dijksterhuis, Bargh, & Miedema, 2000). Colcombe's finding that subliminally priming faces of African Americans led Caucasian participants to perform more poorly than control participants on a mathematics test, but better than controls in tests of rhythm memory and basketball shooting, is also consistent with this interpretation. That is, African Americans are stereotypically disinterested in intellectual achievement while valuing musical and athletic ability. Therefore, priming the stereotype activated these values, and the accessibility of these values affected the effort that participants expended on the task they were given to perform. Other findings confirm this view. For example, subliminally priming faces of Asians, who stereotypically attach high value to intellectual achievement, led participants to perform better on a mathematics test than control subjects (see Wyer, 2004). Furthermore, priming the stereotypes of a punk decreased performance on an analytical task but increased performance on a creativity task, whereas priming the stereotype of an engineer had the opposite effects (Förster, Friedman, Butterbach, & Sassenberg, 2005).

These findings clearly have implications for the effects of movies and television on both consumption and other behavior. They could also account for the effects of unobtrusively placing brands in the context of television shows to which they are objectively irrelevant. However, it is important to keep in mind that priming concepts in themselves are often not sufficient to activate behavior unless the behavior is appropriate in the situation at hand. Thus, activating concepts of African Americans doesn't lead people to express hostility unless the situation with which they are confronted is frustrating or in other ways conducive to the behavior. As Colcombe's research shows, priming the same concepts in other situations can have quite different effects.

The situational cues that determine the activation of prime-related behavior may be internally generated. Strahan, Spencer, and Zanna (2002), for example, showed that subliminally priming thirst-related words led participants to drink more of a beverage they were provided during the course of a simulated taste test. However, this was only true when participants had gone without drinking for several hours prior to the experiment and, therefore, were thirsty at the time the priming occurred. A contingency in these effects may be the extent to which persons are generally

sensitive to internal cues; DeMarree, Wheeler, and Petty (2005), for example, found that priming effects on behavior were less evident among high self-monitors, who typically focus their attention on external cues, than among low self-monitors.

Be that as it may, both Colcombe's and Strahan et al.'s studies both indicate that behavior is determined by both activated knowledge and situational features *in combination*. In considering the implications of this work for consumer behavior, therefore, it would be a mistake to assume that activating concepts and knowledge will stimulate purchase or consumption behavior in the absence of a stimulus situation in which these behaviors are appropriate.

EFFECTS OF BODILY FEEDBACK ON INFORMATION PROCESSING

One of the more interesting areas of research to emerge in recent years has concerned the impact of bodily feedback on judgments and behavior. Bodily movements (e.g., flexing or extending the arm, or shaking or nodding the head) can elicit proprioceptive feedback. This internally generated stimulation can serve as features of a cognitive production that, in combination with other stimulus features, spontaneously elicit a sequence of behavior. Furthermore, this can occur without conscious awareness.

Förster and Strack (1996), for example, showed that when participants were unobtrusively induced to nod or shake their heads while learning a list of positively- and negatively-valenced words, they had better memory for the words that were compatible with the implications of their head movements. Similarly, people were better able to generate names of liked celebrities when they were flexing their arms (a behavior associated with approach) than when they were extending them (a behavior associated with avoidance), but were better able to generate disliked celebrities in the latter condition than in the former (Förster & Strack, 1997, 1998). Analogous effects have been identified in research on consumption behavior. For example, people drink a larger amount of a positively flavored drink if their arms are flexed than if they are extended (Förster, 2003). The approach tendency that was associated with the bodily feedback was apparently restricted to positively valenced stimuli, however. Arm flexion or extension had no impact on drinking behavior when the drink was neutral in taste.

The influence of proprioceptive feedback is not restricted to the activation of cognitive productions, of course. It can also exert an influence behavior through its informational properties. For example, people who nod their head while engaging in cognitive activity may perceive themselves to approve of the activity and, as a result, may be more influenced by its implications. Brinol and Petty (2003) unobtrusively induced participants to nod or to shake their head while listening to a persuasive message that contained either strong or weak arguments. Participants were more inclined to agree with the position advocated in strong-argument messages if they nodded their head while listening to them. However, they were *less* inclined to agree with the position advocated in weak-argument messages in these conditions. Apparently, participants were disposed to elaborate the positive implications of strong arguments but to counterargue the implications of the weak arguments. The proprioceptive feedback associated with head nodding increased their confidence in the implications of these cognitive responses and, therefore, increased the use of these implications as a basis for judgments.

CHAMELEON EFFECTS

According to Prinz's (1990) conceptualization of observational learning, a direct link can often be established between others' motor behavior and one's own. This could occur even if the behavior

in question is incidental. This possibility is suggested by the “chameleon effect,” that is, a tendency to unconsciously imitate the nonverbal behavior and mannerisms of other persons in the situation with whom one interacts (Chartrand & Bargh, 1999; for a review, see Chartrand, Lakin, & Maddux, 1995). Thus, for example, participants in a group discussion are more likely to cross their legs or stroke their chin if others in the discussion are doing so. Similar effects have been investigated in consumer behavior research. Johnston (2002), for example, found that people ate more ice cream in the presence of a confederate who did likewise. Ferraro, Bettman, and Chartrand (cited in Chartrand, 2005) found that participants’ choice of snacks was unconsciously influenced by another’s choices in the same situation. There are undoubtedly analogous effects outside the laboratory. People at a party, for example, are more likely to eat or drink if others are doing so than if they are not. Similarly, people are more apt to make purchases if they are accompanied by other individuals who are on a shopping spree. Although there are obviously other explanations of these phenomena (e.g., bowing to social pressure), the role of nonconscious imitative behavior in a consumer context is worth examining.

IMPULSIVENESS

The role of accessible concepts and knowledge on the spontaneous activation of behavior is particularly important in conceptualizing the antecedents of impulsive consumption (Rook & Fisher, 1995). Several conceptualizations of impulsiveness have been proposed (Baumeister, 2002; Baumeister & Vohs, 2004; Carver, 2004; Strack & Deutsch, 2004). These conceptualizations have typically focused on the antecedents of behavioral self-regulation. In many instances, the behavior can be conceptualized in terms of individual and situational differences in the types of cognitive productions that are activated in the situations at hand.

In a conceptualization of impulsive eating behavior, Schachter (1968; Schachter & Rodin, 1974) identified individual differences in obesity that were traceable to differences in the sensitivity to internal vs. external stimuli. Specifically, obese individuals’ behavior is generally influenced by external stimulus features, whereas nonobese persons’ behavior is more influenced by internal cues. Thus, for example, obese persons’ eating behavior is relatively more influenced by the physical attractiveness of the food, and by the time of day (as indicated by a clock on the wall), whereas nonobese individuals’ eating is more influenced by knowledge of the food’s nutritional value, or by how hungry they feel. These differences could be conceptualized in terms of individual differences in the sorts of cognitive productions that guide behavior in the situations in question.

Although an analysis of impulsive purchase behavior is beyond the scope of this chapter, it may be conceptualized in similar terms. That is, purchasing, like eating, may be governed by cognitive productions that are activated by a configuration of both external and internally generated stimulus features. Different configurations of situational features may activate different productions and, therefore, influence the occurrence of the behavior. Luo (2005), for example, found evidence in a scenario study that persons report a greater tendency to engage in impulsive buying in the presence of peers, but less tendency to do so in the presence of family members, than in other conditions. Moreover, this was particularly true when the purchasers were generally susceptible to social influence and the individuals they imagined accompanying them were cohesive. If participants’ self-reported behavior in imagined purchasing situations reflects their actual purchasing dispositions, Luo’s findings would be consistent with the possibility that different cognitive productions are spontaneously activated, and generate different sequences of behavior, depending on the specific individuals who happen to be present in the purchase situation.

GOALS AND MOTIVES

The influence of accessible knowledge on goal-directed behavior can be of two types. First, as noted in the previous section, goal-directed sequences of behavior may exist in memory in the form of cognitive productions that are activated spontaneously by a configuration of both situational features and other concepts and knowledge that happen to be accessible at the time. The latter concepts can be activated in any number of ways. Fitzsimons and Bargh (2003), for example, found that stimulating participants to think about their mother led them to try harder to succeed in a later achievement situation. Bargh et al. (2001) showed that goal-directed consumption activity could also be activated without awareness. In a particularly interesting study, Fitzsimons, Chartrand, and Fitzsimons (2005, cited in Chartrand, 2005), subliminally priming logos of Apple (a company associated with innovativeness), led individuals to generate more unusual uses of an object in a subsequent creativity test.

The assumption that these effects are mediated by cognitive productions should be qualified. As Bargh et al. (2001) note, a distinction may need to be made between the activation of a goal *per se* and the activation of other types of mental representation. As implied by Principle 2, the effects of activating most representations of knowledge decrease over time. In contrast, the salience of a goal may have increasing effects over time as long as the goal is not satisfied. Results reported by Bargh et al. (2001) and Chartrand, Huber, and Shiv (2005) suggest such increases. Therefore, the interpretation of such effects in terms of cognitive productions is not completely clear.

However, goals, and the sequence of steps required to attain them, are also part of declarative knowledge, and can exist as mental representations in memory. This possibility is implicit in Schank and Abelson's (1977) conception of a cognitive script and its relation to plans, goals and behavior. That is, prototypic sequences of events (e.g., the actions that occur when visiting a restaurant) could exist in memory and be used not only to predict and explain others' behavior but as guides to one's own goal-directed activity. Evidence of the existence of these representations has been obtained by Kruglanski et al. (2002). They found that subliminally priming concepts associated with a goal increases the accessibility of concepts associated with the means of attaining it. In addition, priming concepts associated with means increases the accessibility of concepts that are associated with goals to which they are relevant.

A goal can be viewed as a concept of a desirable state, along with a series of behavioral events that, if they occur, lead to the occurrence of this state (Shah, Kruglanski, & Friedman, 2003; Wyer & Srull, 1989). To this extent, concepts associated with the end state may activate a sequence of behaviors that could potentially attain it (Chartrand & Bargh, 2001). Furthermore, thoughts about the means of attaining a goal may activate concepts associated with the goal itself (Kruglanski et al., 2002), and these concepts, once activated, not only can facilitate goal-directed behavior to which they are relevant but also can interfere with goal-directed activity to which they are not relevant (Shah & Kruglanski, 2002, 2003).

Goals, and the behavior that facilitates their attainment, can be represented in memory at several levels of specificity (Vallacher & Wegner, 1987). Moreover, they may vary in their immediacy. In many instances, a plan-goal hierarchy may exist with more specific and immediate goals serving as means to the attainment of more general, long-range goals (Srull & Wyer, 1986). Thus, studying may be a means of attaining a good grade in calculus, which is a means of attaining the goal of getting into graduate school, which is a means of getting a well paying job, etc.

CULTURAL AND SOCIAL INFLUENCES ON REGULATORY FOCUS

At the most general level, behavior is likely to be governed by a desire to maximize pleasure and minimize pain. However, many behaviors have both costs and benefits, and so the behavior that

potentially has the most desirable consequences can have undesirable consequences as well. Under these circumstances, a person's choice can depend on which set of consequences is more important.

The relative emphasis placed on positive vs. negative outcomes of a decision has been conceptualized in some detail by Higgins (1997, 1998). Specifically, people who are confronted with a decision may be *promotion* focused. That is, they may be motivated by the positive consequence of a decision while ignoring the negative consequences that might result. Others, however, may be *prevention* focused, or motivated by the desire to avoid negative consequences of a decision while giving relatively little weight to the positive effects it might have. Chronic individual differences in these motivational orientations may exist (Higgins et al., 2000). On the other hand, the motivational orientations can also be influenced by situational factors that make one or another set of criteria accessible in memory (for example, whether alternative outcomes are framed in terms of gains vs. nongains or losses vs. nonlosses; Idson, Liberman, & Higgins, 2000; Lee & Aaker, 2004; Monga & Zhu, 2005). Furthermore, once these orientations are activated, their effects may generalize over domains, affecting decisions in situations that are quite unrelated to the one that stimulated them (Briley & Wyer, 2002). A specification of these dispositions and the factors that activate them has obvious implications for an understanding of consumer decision making. Many products have both positive and negative features, and a decision to choose one product over another can often depend on which set of features is weighted more heavily.

Cultural Influences on Goal Accessibility

Chronic dispositions to emphasize the positive or negative consequences of a behavioral decision may be acquired through social learning. Asians, for example, are typically more concerned with negative consequences of their behavior than their North American counterparts (Aaker & Lee, 2001), a tendency that may be traceable to differences in early childhood socialization practices (Miller, Wiley, Fong, & Liang, 1997; for a discussion, see Wyer, 2004). If this is so, they may be relatively more inclined than Americans to focus on the avoidance of negative outcomes. Studies by Briley, Morris, and Simonson (2000, 2005), however, suggest that these different dispositions are often not apparent unless situational factors lead them to be activated. In one study, for example (Briley et al., 2000), Asian and European Americans were asked to choose between two products whose values along a given set of dimensions varied in the following pattern:

	Option A	Option B	Option C
Dimension 1	+3	-3	+1
Dimension 2	+3	-3	-1
Dimension 3	-3	+3	+1
Dimension 4	-3	+3	-1

In such a situation, participants who focus on the desirability of positive outcomes (or, in other words, are "promotion focused;" see Higgins, 1997) should choose either A or B, whereas those who focus on the avoidance of negative outcomes (or, alternatively, are "prevention focused") should choose C. In fact, the groups of participants did not differ in their preference of these alternatives when they were asked to make choices without much deliberation. When they were asked to give a reason for their choice, however, European Americans increased their preference for A and B, whereas Asians increased their preference for C.

These data are consistent with the conceptualization of culture proposed by Hong and Chiu (2001). They note that cultural values, like other concepts and knowledge, are not automatically applied in making judgments and decisions. Rather, these values may vary in their accessibility in memory, and their effects may be overridden by the effects of other more accessible dispositions unless participants are required to draw upon these values in order to justify their choices to others.

Differences in the accessibility of cultural norms may be particularly evident when individuals belong to a bicultural community in which different, often competing norms may be operating. In this case, situational factors may influence the specific norms that are most accessible and, therefore, are most likely to be applied (Hong, Morris, Chiu, & Benet-Martinez, 2000). In a second series of studies, Briley et al. (2005) asked bilingual Hong Kong students to make choices in the situation just described. Participants were more likely to choose the high reward alternative (A or B, in our example) when the experiment was conducted in English than when it was conducted in Chinese, suggesting that the language in which the study was conducted activated norms associated with this culture and consequently stimulated the use of decision criteria that were characteristic of it. Subsequent experiments by Briley et al. (2005) suggested that the language of the experiment activated different expectations for whether responses were socially desirable, and participants conformed to these expectations. Nevertheless, the results are consistent with the conjecture that situational factors influence the accessibility of promotion- and prevention-focused decision criteria.

Effects of Group Salience on Goal Accessibility

Cultural and social norms that are accessible in memory may influence behavior independently of whether people are aware of the factors that lead these norms to be activated. That is, Asians do not need to be aware of their identity as Asians, or Americans of their identity as Americans, for the norms that predominate in these cultures to have an impact. In fact, if participants are made aware of their cultural identity, it may have effects that override the impact of normative factors. Briley and Wyer (2002) found that participants who were led to believe that they were participating in the experiment as members of a group were more likely both (a) to endorse behaviors in an interpersonal situation that minimized inequalities among participants, and (b) to avoid the risk of negative consequences in an individual product choice situation. These data suggested that consciousness of group membership increased feelings of social responsibility and, therefore, the tendency to minimize risk of negative decision consequences in both interpersonal situations and product choices. This was true when this consciousness was induced both by having participants take part in a group activity before performing the decision tasks and by exposing them to cultural icons that made them aware of their cultural identity. (Thus, for example, both Chinese who were made aware of their identity as Chinese, and United States participants who were made aware of their identity as Americans, were more inclined than control participants to make choices that minimized the likelihood of negative consequences.)

In sum, the research by Briley and his colleagues provides evidence that once the motivational dispositions identified by Higgins are activated, they influence decision strategies that generalize over quite different types of choice situations that are unrelated to the conditions that led these dispositions to be activated. As noted earlier, however, cultural norms, or the salience of group membership, are only two of many factors that could activate a prevention or promotion focus and the decision strategies that are associated with them. The influence of these factors on product evaluation and purchase decisions is worthy of further investigation.

EFFECTS OF TERROR MANAGEMENT ON MATERIALISTIC MOTIVES

A quite different area of research on goal activation has direct relevance to consumer behavior and decision making. This research has largely been performed within the framework of terror management theory (Solomon, Greenberg, & Pyszczynski, 1991; for discussions of its implications for consumer behavior, see Arndt, Solomon, Kasser, & Sheldon, 2004a,b; Maheswaran & Agrawal, 2004; Rindfleisch & Burroughs, 2004). According to this theory, activating concepts associated with death increases concerns about one's personal mortality. This, in turn, increases the need to maintain self-esteem and to engage in consumption behavior that will enhance this esteem. Mandel and Heine (1999), for example, found that completing a measure concerning fear of death increased participants' attraction to high status products (e.g., Rolex watches) but had no effect on their liking for products that were not status-related.

Ironically, the effects of mortality-related concepts on consumption behavior are evident even if the consumption is deleterious to one's health and, therefore, potentially detrimental to one's longevity. Goldenberg, Arndt, and Brown (2004) found that women who had been primed with thoughts about death were less inclined to eat foods that were described as nutritious but likely to compromise the attractiveness of their figures. Similarly, priming mortality-related concepts increased participants' desire to purchase products that would increase their sun tan despite the fact that they would also increase the risk of skin cancer (Routledge, Arndt, & Goldenberg, 2003). Although the mortality-related concepts that produced these effects in the laboratory were situationally primed, it seems reasonable to assume that chronic concerns about death can give rise to a more general materialistic motive that influences consumption behavior in numerous situations outside the laboratory.

THE INFLUENCE OF AFFECT ON GOAL-DIRECTED ACTIVITY

The goals that people pursue, and the effort that they devote to their attainment, can be influenced by the affective reactions they are experiencing at the time. Isen (1987) and her colleagues (Isen, Daubman, & Nowicki, 1987) found that happy individuals perform better on creativity tasks, suggesting that positive affect influences the ability and/or motivation to think innovatively. In many cases, however, the influence of affect on goal-directed behavior can result from its use as information about whether the behavior is effective. That is, people who are engaged in goal-directed activity may implicitly ask themselves if they feel that this activity is effective, and may use the affect they are experiencing as a basis for answering this question. Consequently, it may influence the extent to which they continue the activity or stop.

A series of studies by Martin, Ward, Achee, and Wyer (1993) provide evidence of this possibility. In one study, participants who had been induced to feel happy or sad were asked to form an impression of someone on the basis of a series of behaviors, each conveyed by a different card in a deck. In some conditions, they were told to turn over one card at a time and continue to do so until they felt they had formed a good impression. In other conditions, they were told to continue as long as they were enjoying themselves. In the first case, participants stopped sooner if they felt happy than if they did not, suggesting that they used the affect they were experiencing as a basis for deciding if the impression they had formed was good enough. In the second condition, however, participants spent longer on the task if they felt happy, suggesting that in this case, they used their feelings as a basis for deciding if they were enjoying what they were doing.

Similar results were obtained in a second study in which participants were asked to generate uses of a brick. That is, participants who had a performance goal generated fewer uses if they felt

happy than if they did not, whereas participants who had an enjoyment goal generated more uses if they felt happy than they did otherwise. Results of numerous studies on the influence of affective reactions on goal-directed behavior can be interpreted in terms of the impact of these reactions on the evaluation of this behavior or its consequences (for reviews, see Wyer, 2004; Wyer et al., 1999). Its implications for consumer behavior are obvious. For example, people who go shopping for enjoyment are likely to spend more time in the activity if they are happy than if they are less so. In contrast, people who go shopping with the goal of buying a particular product are likely to spend *less* time in the activity if they are happy than if they are not.

CONCLUDING COMMENT

This chapter has covered a lot of ground. Yet, it has not begun to capture the number and diversity of phenomena that are directly and indirectly influenced by the concepts and knowledge that people happen to have accessible in memory at the time they are called upon to make a judgment or decision. Readers of this chapter will inevitably identify many important areas of research, in consumer behavior, and other areas, in which knowledge accessibility can play a role. The purpose of this chapter is primarily to call attention to the importance of taking into account both situational and individual differences in knowledge in conceptualizing the determinants of consumer judgment and decisions and the processes that underlie them.

The effect of knowledge accessibility on judgments and behavior is so well established that its existence can be taken as a given. In fact, as pointed out elsewhere (Wyer, 2004), the effect can often be used as a diagnostic tool in determining the causal relatedness of factors on judgments and behavior under conditions in which this relatedness is otherwise hard to establish. As Principle 1 implies, only a subset of the factors that influence a judgment or decision are likely to come into play at any given time. However, if a particular factor is among those that potentially affect a given behavior, increasing its accessibility in memory should increase the likelihood it is used as a basis for this behavior. If, on the other hand, the factor is *not* a determinant of the behavior, increasing its accessibility should have no effect. This strategy is of particular value in examining the determinants of behavior outside the laboratory.

This strategy was first employed by Schwarz and Strack (1981) to demonstrate the causal influence of a coercive government policy on people's willingness to sign petitions on a controversial social issue, and by Wyer, Bodenhausen, and Gorman (1985) in diagnosing the cognitive mediators of reactions to rape incidents. More recently, it was used by Shrum et al. (1998) to demonstrate the causal influence of television viewing on perceptions of social reality, and by Yeung and Wyer (2005) to confirm the impact of affective reactions to a brand name (as opposed to specific brand-related features) on evaluations of a brand extension. Knowledge activation techniques are likely to be useful in understanding a variety of relations among variables that are naturally confounded in every day life experience and cannot be directly manipulated. Their use in a consumer context may therefore be worthy of consideration.

ACKNOWLEDGMENT

The writing of this chapter, and some of the research discussed therein, was supported by grants HKUST6053/01H, HKUST6194/04H, and HKUST6192/04H from the Research Grants Council, Hong Kong. Appreciation is extended to Jens Förster and Frank Kardes for comments on an earlier draft of this chapter.

CAROLYN YOON

University of Michigan

The systematic study of consumer behavior is heavily influenced by theories and paradigms from memory research, as the behavior of the consumer is largely influenced by prior experiences. The distinction is often drawn between memory-based, stimulus-based (all relevant information is physically present at the time of judgment or choice), and mixed (a combination of memory-based and stimulus-based) decisions (Lynch & Srull, 1982). However, purely stimulus-based decisions are relatively rare; most consumer decisions are necessarily dependent on memory and thereby range from the purely memory-based to mixed (Alba, Hutchinson, & Lynch, 1991).

Given the importance of memory in consumer research, it behooves us periodically to take stock of the contemporary theories of memory and consider their assumptions and implications. To that end, we aim in this chapter to provide a review of the dominant accounts of memory and the way they have shaped our understanding of consumer behavior in the past two decades. We discuss the advances that have been made as well as some areas of potential concern. Specifically, we frame the review and discussion vis-à-vis an alternative account of memory, the SCAPE framework, developed by Bruce Whittlesea and his colleagues (e.g., Whittlesea, 1997). In addition, we offer some suggestions and future directions for research on consumer memory.

MEMORY

Memory is the record of our personal past. As such, it is useful for remembering. But memory is also much more than that: it also involves the capacity to learn, to be influenced by prior experience, and to behave differently in the future as a consequence of an experience. Memory is the controller of all acquired human behavior, including speech, conceptual knowledge, skilled activities, social interactions, and consumer preferences. To achieve a true understanding of any aspect of human behavior, it is therefore essential to have an effective theory of memory.

During the 1970s, the notion of associative memory was introduced (Anderson & Bower, 1973). Following the assumption that elaboration is related to the creation of associative pathways in memory; the notion that elaboration could impact attitudes became an important research question. Elaborative processing became a heavily studied determinant of information accessibility (e.g., Kardes, 1994) and attitude formation (Kisielius & Sternthal, 1986; McGill & Anand, 1989). Such effects have been explained by a multiple-pathway explanation (cf. Anderson, 1983), although more recently explanations have favored the reconstruction hypothesis (e.g., Walker, 1986).

Despite the popularity of thinking about memory in terms of “construction” (e.g., Loftus & Palmer, 1974; Loftus, 1979), during the 1980s, “separate systems” approaches to memory became popular, and continue to be popular today. We will focus on these approaches: first outlining them in detail, and then contrasting them with the SCAPE framework.

SEPARATE SYSTEMS THEORIES

Three major dichotomies were proposed as the basic organization of memory, each pointing to some clear contrast in behavior. Each dichotomy is based on observations of various dissociations in performance on some tasks. For example, recognition performance has been found to be affected by varying levels of processing (Jacoby & Dallas, 1981) or delay of test (Tulving, Schacter, & Stark, 1982) while leaving identification performance unaffected. Amnesic patients demonstrate implicit learning (Knowlton & Squire, 1994) and respond to repetition priming (Warrington & Weiskrantz, 1970), despite poor recognition performance. These dissociations are taken as evidence of Nature’s seams, the lines along which mind can be split and compartmentalized into convenient and independent sub-units, each of which can be studied without consideration of the other.

The *episodic/semantic* dichotomy of memory is arguably the most dominant of the three dichotomies. It distinguishes the preservation of detail and context of prior experiences from the preservation of context-free, abstract, summary properties of those experiences (e.g., Tulving, 1983, 1985). The former supports tasks such as recall and recognition; the latter supports tasks requiring perception, identification, and conceptual and categorical knowledge.

Also common is the *procedural/declarative* dichotomy which is based on the distinction between a declarative system, supporting tasks requiring conscious deliberation about the content and source of current knowledge, and a procedural system, supporting tasks requiring specific skills, or motoric ability (Cohen & Squire, 1980). The distinction is between intentional acquisition, storage, and retrieval of information versus non-reflective acquisition and application of prior experience, as evidenced by perceptual, cognitive, and sensorimotor performance on tasks demonstrating skill or involving repetition priming. *Skill* is considered to be a product of multiple prior experiences; *priming* is considered to be a product of a single prior experience. Evidence of either is measured by the observed savings or facilitation in performance, in the absence of conscious awareness, control, or volition.

The third dichotomy entails an *implicit/explicit* distinction that emphasizes the differential role of consciousness in performance, contrasting tasks such as recall and recognition, in which awareness of prior experience is important, versus tasks which measure repetition priming (Graf & Schacter, 1985). An implicit form of memory exists to account for effects of prior experience on current behavior in the absence of conscious awareness (e.g., effects observed in a priming task); an explicit form of memory exists to account for behavior accompanied by conscious awareness (e.g., effects observed in a remembering task).

These separate systems theories of memory are based on the assumption that the fundamental functions of mind are obvious: they consist of the capacity to perform each of the various activi-

ties that humans are faced with in the social world, such as recognition, knowing, and responding appropriately but unconsciously in skilled activities such as speech and dance. The important research question is thus not what the functions of mind are, but how they are performed. It has further been assumed that different functions of mind are served by separate dedicated mechanisms, and that the dissociated patterns of performance observed in performing various tasks is a consequence of the different principles by which the separate mechanisms work. Finally, because of this correspondence of mechanism with function, it has been assumed that each mechanism serves each function directly. Thus, for example, because recognition of a particular face or event requires differentiation among many others, that function is served by a specific retrieval mechanism; whereas classification of an object such as a dog in the street could benefit from experience of many similar beasts, and so instead relies on abstraction of knowledge across events and activation of a general concept node.

Applied to consumer memory, the separate systems distinctions have been useful for compartmentalizing consumer knowledge. For example, a “retrieval set” is distinguished from a “knowledge set” (e.g., Alba & Chattopadhyay, 1985), or a “consideration set” is distinguished from an “awareness set” (see Shapiro, MacInnis, & Heckler, 1997). In each example, the former is episodic in nature, the latter semantic. As such, the assumptions of the distinction are often used for hypothesis testing, and taken for granted. For example, many consumer researchers assume that activation of nodes in semantic memory is a necessary by-product of cueing to a brand category or feature (e.g., Cowley & Mitchell, 2003; Nedungadi, 1990; Shapiro, 1999), and often discuss “activation” as a causal mechanism, rather than a proposed theoretical construct.

This chapter argues that current major theories of memory are problematic, and instead favors an account of memory called SCAPE, which is an acronym for “Selective Construction And Preservation of Experiences” (Whittlesea, 1997). This account is a synthesis of ideas from the attribution theory of remembering (e.g., Jacoby & Dallas, 1981; Jacoby, Kelley, & Dywan, 1989; Whittlesea, 1993), the episodic-processing account of concept acquisition (e.g., Whittlesea & Dorken, 1993), instance theory (e.g., Brooks, 1978; Medin & Schaffer, 1978; Jacoby & Brooks, 1984), skill transfer (e.g., Kolars & Smythe, 1984), and transfer-appropriate processing (TAP; e.g., Morris, Bransford, & Franks, 1977; Roediger & Challis, 1992; Masson & MacLeod, 1992). In accordance with the SCAPE framework, we suggest that the functions of mind identified by separate systems (and most contemporary) theories are misleading: they are categories of mental performance that make sense from the point of view of the user of memory (one’s conscious self), but do not correspond in any direct way with the fundamental principles of memory. We further argue that the real underlying mechanisms of memory are unitary and serve all of these user-defined functions; and moreover that they do so indirectly, such that the mechanism responsible for a certain behavior in no way resembles the behavior. Among other claims, we deny that remembering consists of retrieval; that spreading activation and inhibition are valid mental operations; that conscious and unconscious performance have different causal agents; and that controlled and automatic behavior differ in any meaningful way.

A FUNCTIONAL ANALYSIS

However obvious the contrasts between explicit and implicit performance, or between remembering and knowing, it will be argued in this chapter that none of those are fundamental functions of mind. Instead, they are emergent categories of behavior, useful in describing differences in a person’s behavior from the outside, and perhaps in describing their current intentions, but not diagnostic of the underlying principles by which mind is organized. The problem, we assert, stems from

a levels-of-analysis problem, confusing what a system achieves in operating on the world with the means by which that operation is attained. To take a simple example of the problem, in attempting a functional analysis of an automobile, one might perform an examination of the variety of things that cars are used for. Following such an examination, one might be tempted to say that a car's chief functions are transportation, ego projection, sport, and courtship. Certainly these are valid and separate categories of interaction with the world that cars enable us to achieve. However, they do not reveal anything about the underlying affordances that support these achievements (capacities such as steering, propulsion, shock absorption, and containment), and even less about the mechanisms that support these affordances (rack and pinion steering, disk brakes, Otto-cycle engine, and so on). That is, the functions of a system that are evident to and of value to the user of the system may not in any way resemble the basic principles by which the system operates. In consequence, arguing basic mechanism from dissociations among classes of activity that are important to the user is fraught with danger.

More important, we believe that Nature, in her subtlety, often arranges for behaviors that are of advantage to her offspring to come about in ways that are startlingly indirect. As an example, consider a well-known phenomenon: that of a sunflower's tendency to follow the path of the sun over the course of a day, known as *heliotropism*. A direct mechanism to bring about this correspondence would require, in addition to some mechanical means of twisting, (a) that the plant knows, at a given moment, where the sun is, (b) that it also knows the direction in which it is currently pointed, and (c) that it has some means of calculating the difference. Clearly, such a direct mechanism is wrong. In fact, the mechanism is indirect, having the *effect* of bringing about alignment with the sun without any computation of that alignment. The actual, more subtle, explanation of this behavior is that red and blue wavelengths of light respectively increase and reduce photosynthesis and the resulting uptake of water into the stem's cells. The gradient of blue light across the plant stem in full sunlight causes cells on the shady side of the stem to increase photosynthesis and water uptake, expanding their size, whereas photosynthesis in cells on the sunny side is reduced, leading these cells to shrink. This combination of effects causes the head of the plant to twist, bending toward the sun. That the plant faces the sun accurately is in some sense an accident, resulting from the ratio of swelling in cells on opposite sides of the stem; the real cause of that effect is that ancestral sunflowers that had better ratios of swelling, so that they followed the sun more precisely, out-competed those that did so less effectively. Thus, the success in sun-following, although vital to the plant, is better thought of as an incidental benefit or by-product of its fundamental architecture, rather than as an inherent function of that architecture.

These two examples illustrate the difficulty of functional analysis aimed at understanding the fundamental principles of a system that control that system's interactions with the world. We will propose a different dichotomy of functions of mind, of production versus evaluation, that is fundamental to the SCAPE framework of memory (Whittlesea, 1997). This dichotomy is much more abstract than any of those recounted earlier, and much less easily tied to any specific behavior that a person performs. However, we will argue that it provides a more thorough explanation of the variety of human performance than do any of the other so far mentioned accounts.

THE SCAPE FRAMEWORK

According to the SCAPE account, there is only one memory system, which contains only representations of the experience of processing the stimuli in various tasks and contexts. In any processing event, this memory system interacts with the environment; the environment constrains some activities and affords others (e.g., you can use a pencil as a weapon or to stir coffee, but cannot fly on

it). The central function of memory is *construction*: memory never simply registers or records the environment, but instead imposes selection, organization, and meaning on it. It is this experience of construction that will be encoded in memory, and that will control performance on subsequent interactions involving stimuli, tasks, and contexts that are similar on relevant dimensions.

The construction function has two aspects: (1) the *production* of psychological events, controlled by the interaction of the stimulus, task, and context, with representations of previous processing experiences in memory; and (2) the *evaluation* of the significance of that production, given the stimulus, task, and context. The former leads to performance: the occurrence of all manner of perceptual, cognitive, and motoric events. The latter results in phenomenology: the subjective reaction to current processing that causes people to adopt the attitude that they are remembering, understanding, or identifying an object, either correctly or committing an error.

The production function begins by selecting some aspect of the current situation as a stimulus, or focus of attention, the rest as context. This selection depends on a variety of factors, including the prior history of memory with various aspects of the environment, each aspect's salience or apparent significance (threat, novelty, interest), and the preparedness of the system to perform some activity given how and what it has just been processing. This process continues on to construct a mental model of the event: of a percept of the stimulus, of its identity, class or covert properties, or of the detail of a past or future event involving that stimulus, depending on the task at hand and the affordances and cue properties of the stimulus and context.

Many accounts of memory involve (at least in part) assumptions that sound similar to those just stated. However, the SCAPE account makes two radical claims. The first is that current cognitive processing is always the product of a constructive act. One implication is that, although a prior episode can, in part, control the shape and ease of constructing a mental model of a current stimulus, that prior episode is not itself retrieved. That has major implications for understanding the nature of remembering, as documented below. A second departure is the account's insistence that the production function is always accompanied by the operation of the evaluation function, although that is often difficult to detect (see Kronlund & Whittlesea, 2005, for a demonstration of this point).

The evaluation function consists of chronic monitoring of the integrity and coherence of ongoing performance; it also makes inferences about unexpected successes or apparent failures of coherence. In the words of Marcel (1983), it consists of an attempt to "make sense of as much data as possible at the most functionally useful level" (p. 238). It is this act of inference which gives rise to the phenomenology accompanying performance. In attempting to make sense of apparent disparities between two aspects of a current stimulus, or between what is expected and what occurs, the evaluation function makes an attribution to some plausible source of influence. The apparent disparity may be resolved by an attribution to the stimulus, the situation, the person, or the past; these unconscious attributions give rise to conscious feelings such as desirability, impending danger, unusual mood, or familiarity.

THE CONSTRUCTIVE NATURE OF AWARENESS

According to separate systems accounts, explicit and declarative knowledge is thought to be accessed by retrieval. In contrast, the SCAPE account assumes that information is never retrieved, but constructed. This idea was originally proposed by Bartlett (1932), and with some exceptions (e.g., Janiszewski, Noel, & Sawyer, 2003; Braun-LaTour, LaTour, Pickrell, & Loftus, 2004),¹ it is hardly considered in the consumer literature. As an example, imagine that a recognition study begins with a study phase consisting of paired associates, such as onion-carrot, milk-cheese, bread-cake, etc. At test, when asked "Did you see MILK in the earlier list?", one subject may reply

“MILK.....oh yeah, CHEESE. Yes, I do remember seeing MILK.” That performance seems to demonstrate that the person has used MILK as a cue to retrieve the episodic representation of the earlier experience, and that, in doing so, they have become aware of a prior experience. That description of the process is too simple, however. Another subject might respond “MILK, um, CHEESE, um, no, that’s just a common associate. I don’t remember MILK.” That subject’s initial performance duplicates that of the first subject’s. However, although the content of the earlier experience comes to mind, this person has not become aware of the prior experience. Another subject might say, “MILK — oh right, DAIRY. Yes, I do remember seeing MILK.” This person’s performance is influenced by a source other than the specific prior experience, yet this person is experiencing awareness of encountering that item.

These examples demonstrate that becoming aware of a prior experience is caused by two inter-linked processes: the production of a response, and an evaluation of the significance of that production. The coming-to-mind of an item in a remembering task is thus not one and the same as awareness of the prior event. Awareness of the source of the production comes about by an evaluation of the significance of that production, which results in an attribution to a source that seems most likely.

As another illustration of the difference between these two aspects of construction, Leboe and Whittlesea (2002) presented subjects with pairs of items: one-third contained two strong associates (e.g., LION-TIGER), one-third contained two unrelated words (e.g., ROAD-NAVY), and one-third contained one word and four Xs (e.g., TABLE-XXXX). Each associate in the former two cases occurred only once in the study phase, whereas XXXX occurred on many study trials. At test, subjects were provided with a word stem (e.g., LION-?) and were required to recall the item with which it was paired earlier, and provide a confidence rating about their performance. Subjects performed accurate recall on 48% of the trials involving strong associates, on only 13% of the trials involving unrelated words, and on 41% of the trials involving XXXXs. In contrast, subjects’ confidence ratings for those trials were 78% for recall of the strong associates, 91% for recall of the unrelated words, and only 45% for recall of XXXXs.

Leboe and Whittlesea concluded that the differential rates of recall accuracy and confidence reflect the interaction of two operations: the coming-to-mind of a response (i.e., a strong associate, an unrelated word, or XXXX), and the subject’s resulting evaluation of the significance of each of those types of responses coming to mind. For example, subjects were unimpressed with the coming-to-mind of XXXX, because they were aware that they could easily generate it because of their knowledge that one-third of studied items were paired with XXXX. Thus, they often produced XXXX correctly, but even when accurate, they were not convinced that they were actually recalling. In contrast, recall of an unrelated word was difficult, in part because the association formed during study would often be of low quality (e.g., the association between ROAD and NAVY). Consequently, accurate recall was low in this condition. However, when an unrelated word did come to mind, subjects were very impressed because they could think of no other reason why that word would come to mind other than that it had been presented in study. Such productions were thus experienced as accurate recall, and were associated with high confidence ratings.

Therefore, the conclusion that one is now aware of an aspect of the past is always a decision: an adoption of an attitude toward current processing. Awareness of the contents of previous experiences does not comprise direct access to a representation of the past. It is the product of a heuristic decision. People are chronically having to infer the nature of their past from the quality and content of their current processing. There are always multiple possible reasons why a particular mental event occurs: because it actually occurred in one’s past, because one experienced a similar event

with a different stimulus, because that event occurred in the life of someone else who has told you about it, or because one has experienced many similar events, which in parallel contribute to the ease of processing the current mental event.

This inferential relationship between awareness and experience is not limited to remembering. It is also true of knowledge in general. In the next section, we will demonstrate analogous performance in remembering and classification judgments, but that people claim awareness of the basis of their performance in the first but not the second. The difference appears to be only due to the adoption of an appropriate attitude and theory to understand their performance in the first case and a lack of doing so in the latter.²

SEPARATE SYSTEMS APPROACHES TO MEMORY

Separate-systems accounts of memory, including the episodic/semantic (Tulving, 1983, 1985), declarative/procedural (Cohen & Squire, 1980), and explicit/implicit (Graf & Schacter, 1985) dichotomies, are based on the notion that memory performance is sustained by distinct modules of memory. The modules support different functions of memory, each of which is based on specific types of knowledge, and thus have specific principles for acquiring and applying each type of knowledge. Each type of knowledge is also selectively cued by different types of tasks, and preserved in distinct stores. Evidence for such dichotomies in memory has come from dissociations that have been observed in both intact and amnesic subjects. We provide an in-depth description of the episodic/semantic and implicit/explicit dichotomies, as they have dominated how consumer researchers conceptualize memory.³ We provide empirical evidence for each distinction, and examples of consumer behavior studies which have embraced or relied on each. We focus primarily on studies on consumer memory published since the review by Alba et al. (1991).

THE EPISODIC/SEMANTIC DICHOTOMY

According to this account, memory can be subdivided into an episodic system which preserves details of particular experiences and supports remembering tasks (i.e., recall and recognition), and a semantic system, which preserves conceptual and categorical knowledge and supports non-remembering activities (i.e., perception and identification). The semantic system thus preserves the abstract, context-free, summary properties of all prior experiences (Tulving, 1983, 1985). The fundamental distinction is between *remembering*, which depends on event-specific information, and *knowing*, which depends on the abstracted summary of prior experiences. Event-specific information can take on the form of tokens (Kanwisher, 1987); abstractions can take on the form of types (Anderson, 1980, 1983; Kanwisher, 1987), prototypes (Rosch, 1978), rules (Reber, 1989, 1993), or logogens (Paap & Noel, 1991). The process of acquiring knowledge occurs by automatic abstraction or implicit learning; the process of accessing knowledge is thought to be mediated by the principles of activation and inhibition.

Although not always made explicit, numerous consumer researchers appear to assume an episodic/semantic distinction of memory. A set of studies have examined how brand or product category schemas are formed and organized. For example, Meyvis and Janiszewski (2004) investigated how breadth of brand categories affects brand associations and perceptions of brand extensions (see also Gurhan-Canli, 2003); Wood and Lynch (2002) examined the effects of expertise or prior knowledge about products on learning of new information and subsequent memory; and Roedder-John and Sujana (1990) studied product information organization and categorization in young children.

The strength and extensiveness of information held in memory and how it affects consumers' judgments and decisions are almost always considered to be a direct or indirect function of person-related (e.g., motivation, ability), stimulus-related (e.g., distinctiveness, visual vs. verbal), and situational factors (e.g., time delay, usage situation). For example, Park and Hastak (1994) have examined how involvement affects product memory, and how the product memory affects judgments. Peracchio and Tybout (1996) have also investigated how product category schema affects product evaluations. In particular, they examined the effects of schema incongruity on product evaluations. Thus these consumer studies share commonalities with some aspects of the SCAPE framework. For instance, the production part of construction processes posited by the SCAPE assumes an interaction of stimulus, task, and context that is in line with the approach taken by consumer researchers. However, there is no accompanying acknowledgement in the studies that the significance of the production is, in turn, evaluated.

Other studies have also investigated the manner in which organization of brand information or prior knowledge affects how and what information is processed and remembered by consumers. The way that prior knowledge influences judgments or choice has been of interest to a number of consumer researchers (e.g., Crowley & Mitchell, 2003; Hutchinson, Raman, & Mantrala, 1994; Nedungadi, 1990). These studies, however, largely assume that "retrieval" occurs as the result of a spreading activation process. A threshold level of activation of a particular concept, such as a brand, is assumed to be facilitated through the use of cues such as attribute information. This in turn results in retrieval of the target brand. Spreading activation models have also been applied to models of brand equity (e.g., Aaker, 1991; Keller, 1993, 1998).

In the following sections we describe assumptions made by the episodic/semantic approach that separate principles are involved in remembering and knowing, that acquisition of knowledge occurs by automatic abstraction, and that access to knowledge structures is mediated by activation and inhibition. We consider further examples of consumer behavior studies which have embraced each assumption. We also provide predictions made by SCAPE for each observation discussed.

ACQUIRING KNOWLEDGE STRUCTURES

One observation that suggests the use of abstracted information is *implicit learning* (Dienes & Berry, 1997; Knowlton & Squire, 1994; Reber & Allen, 1978; Reber, 1989, 1993). As an example of what takes place during an implicit learning study, brand logos (e.g., the Hello Kitty picture) are shown to subjects in their regular and opposite orientations (e.g., Hello Kitty with a bow in her hair above her right ear instead of her left ear). Subjects are above chance at choosing the correct orientation, suggesting automatic, incidental learning of regularity in such stimuli (Kelly, Burton, Kato, & Akamatsu, 2001). Such results have also been found in controlled laboratory settings, where attention is directed to stimuli that follow a rule. At test, subjects are above chance at discriminating between legal and illegal items (i.e., they demonstrate sensitivity to the abstract structure of the domain) without having awareness of the rule (e.g., McGeorge & Burton, 1990).

Such performance is taken as evidence that the subjects must have abstracted information about the rule during the exposure phase. Because they are unaware of doing so, that abstraction must be automatic. The phenomenon of implicit learning is thus argued to demonstrate the existence in memory of an autonomous abstraction mechanism that proceeds independent of conscious intention or awareness, and supports performance in tasks such as classification and identification.

The suggestion of automatic abstraction has been criticized on the grounds that test items that are legal are highly similar to each previously encountered legal (studied) exemplar of the given class, therefore, if a subject simply memorizes one or more of the study items, and uses the per-

ceived similarity of test items to those memorized instances as a basis for their decision, they will perform above chance (Brooks, 1978, 1987; Dulany, Carlson, & Dewey, 1984; Neal & Hesketh, 1997; Perruchet & Pacteau, 1991; Shanks & St. John, 1994; Vokey & Brooks, 1992). This provides a situation whereby the same processes that are involved in showing sensitivity to prior individual experiences (episodic) are also involved in showing sensitivity to general, abstract properties of classes (semantic). The SCAPE account is in agreement, but adds that memory preserves processing experiences, and the type of processing experience that occurred on a prior encounter with a stimulus will influence later processing of the same (or a similar) stimulus to the extent that later processing matches the earlier processing experience (i.e., transfer appropriate processing; henceforth TAP; Morris et al., 1977). The SCAPE account suggests that TAP will apply to both remembering and non-remembering tasks (Whittlesea & Dorken, 1993, 1997).

To demonstrate that TAP applies to non-remembering activities such as classification, Wright and Whittlesea (1998) developed a set of four-digit stimuli, each which followed the rule odd-even-odd-even (e.g., 3412, 8954, etc). They presented these items to subjects in a study phase, and encouraged them to read them as bigrams (e.g., “thirty-four, twelve,” etc). At test, no studied items were shown, however, half corresponded to the odd-even-odd-even rule, half violated the rule (e.g., 4613, 8723, etc). Subjects were asked to discriminate legal from illegal items, and they accurately did so 68% of the time, although they were unable to state the rule. This type of finding is usually interpreted as providing evidence for automatic abstraction and subsequent use of a rule in semantic memory. In another study, the same study phase was used. At test, studied (e.g., 3412) and new (e.g., 1374) items were presented; subjects were asked to discriminate studied from unstudied items (i.e., they performed recognition); they accurately did so 71% of the time. This type of finding is usually interpreted as acquisition and use of episodic memory. In a subsequent study, half the subjects were given the identical study and instructions as outlined above (i.e., to read digits as bigrams), the other half were encouraged to read stimuli as individual digits (e.g., “three-four-one-two”). The bigram group classified legal from illegal test items with 70% accuracy, however the digit group had only 58% accuracy. This result demonstrates that representations of particular experiences are determined by the type of task used, and are preserved and demonstrate transfer to both recognition and classification tasks.

In their fourth experiment, they showed subjects digits in a study phase, and encouraged them to read them as bigrams. At test, subjects were able to discriminate legal (odd-even-odd-even) from illegal items at 65% accuracy, but could not state the rule, again suggesting automatic abstraction of the rule. In this study however, the study items all consisted of combinations of odd-odd or even-even bigrams with odd-even bigrams (e.g., 3714, 8432, 6897, etc). Thus, if subjects were abstracting a rule of some sort, it would be “either odd-odd or even-even as one of the two bigrams.”

In this case, Wright and Whittlesea attempted to demonstrate that subjects could *appear* to show sensitivity to a rule (i.e., to a non-existent odd-even-odd-even rule). To achieve this end, they constructed the test items such that both bigrams in the “legal” test items (e.g., 1432) had occurred in several study items (e.g., in 3714, 8432, 7514, etc), whereas the bigrams of the “illegal” items (e.g., 3154) never occurred in any of the study items. Thus subjects could successfully classify the items if and only if they had encoded the instances from study rather than if they had automatically abstracted a rule. The ability of subjects to show above-chance performance at classifying according to the non-existent odd-even-odd-even rule demonstrates that subjects used the similarity of the test items to study instances to classify them.

The important lesson to be learned from these studies is about the nature of awareness. In the initial recognition study, when subjects were told about their above-chance scores, they were unimpressed: when asked for an explanation of their success, they said something like, “Well, I just

remembered them, you know?” In contrast, subjects in the remaining studies were quite mystified when told about their above-chance success. Having not been told any rules, and having not consciously worked out any rules, they could think of no basis for above-chance success, and agreed that they must have learned the rules unconsciously. In fact, the set of experiments taken together suggest that the subjects performed on exactly the same basis in classification as they did in recognition. Why, then, should they not be aware of the basis of their success? We suggest that they adopted an inappropriate theory (as did the original investigators of this effect): that success in classifying according to a rule can occur only if one has the rule. This adoption of an inappropriate theory prevented the subjects from achieving awareness of the basis of their performance. In turn however, that conclusion changes the nature of what is meant by awareness. Rather than being aware or unaware of what we are doing, the question is whether we are aware or unaware of the effect of what we are doing now with respect to some unanticipated decision in the future. Viewed in that way, “awareness” is an attribution, based on an inference, about the significance of our current processing. Thought of in this way, “accessibility” and “diagnosticity” (Feldman & Lynch, 1988) are very complicated processes, which, according to the assumptions of SCAPE, may be based on a person’s intuitive theories of cause and effect, the salient aspects of the current situation, and the current task, which selectively cues prior experiences, both individually and in parallel.

ACTIVATION

In the episodic/semantic view of memory, types, and prototypes are assumed to be stored as nodes in a network organization in memory (e.g., Anderson & Bower, 1973). The knowledge structures are assumed to be hierarchical (thus imposing cognitive economy and inheritance; e.g., Collins & Quillian, 1969; see also Nedungadi, 1990) or non-hierarchical (e.g., Collins & Loftus, 1975). Any prior exposure to an exemplar, associate, or conceptual feature of that node is thought to “activate” that node, adjacent nodes, and closely linked nodes within the network (e.g., Anderson, 1983; Collins & Loftus, 1975).⁴

The associative network model of memory is a common way that consumer researchers have conceptualized the organization of brands and brand-related information in memory. According to this perspective, consumer memory is represented in the form of episodic and semantic traces of the incoming information (e.g., source and content) that comprise schemas or knowledge structures. The fundamental assumption is that consumers hold knowledge structures or schemas that are related to specific consumer domains (e.g., Nedungadi, 1990). When a particular knowledge structure is accessed or “primed,”⁵ the central node and related nodes are activated, and facilitation in processing is observed, either through a direct or indirect test. Basic reaction time measures are often used as the critical dependent measure demonstrating effects of prior experience (e.g., Jewell & Unnava, 2003), and are assumed to be advantageous over other measures (see Fitzsimons et al., 2002).

Instead of facilitation through activation, the SCAPE account argues for overlapping operations (e.g., Hughes & Whittlesea, 2003). No one can become aware of the entire content of their memory. However, it is often possible to be influenced by semantic relationships acquired in the past and to be aware of that influence in current experience. One example of this is the semantic priming effect. Originally explored by Meyer and Schvaneveldt (1971), the effect consists of the facilitation of performing a task, such as naming or lexical decision, when the test stimulus or probe (e.g., DOCTOR) is preceded by a meaningfully or associatively related stimulus, usually referred to as a “prime” (e.g., NURSE). One of the boundary conditions of the effect which has been regularly observed, and has been influential in theories about underlying mechanism, is that it is short-lived, both in terms of absolute time (stimulus onset asynchrony; SOA) and lag (number of unrelated

items inserted between the prime and probe). The effect can disappear when the SOA is as little as 500 ms (Ratcliff & McKoon, 1988); facilitation of the probe is not observed if the presentation of the probe is delayed by more than two seconds (e.g., Neely, 1977, 1991). Further, any amount of lag eliminates the effect (e.g., Masson, 1995), although some investigators have observed priming occurring at a lag of one (e.g., Joordens & Besner, 1992; McNamara, 1992).

The finding of the initial boundary conditions led investigators (e.g., Anderson, 1976, 1983; Collins & Loftus, 1975) to propose spreading activation accounts of the effect. The proposed mechanism at the time was that presentation of the prime activates its node in a semantic network; that activation spreads along the linkages of the network to nodes of all related concepts. As a consequence, the nodes of all related concepts become partially activated, such that they can be stimulated above threshold more quickly than if not primed. By this account, the effect is short-lived because activation dies away quickly in the semantic network.

Whittlesea and Jacoby (1990) presented an alternative account of semantic priming, in which such a time course is not a central issue. This account was based on Kolers' (1973, 1976) idea of "remembering operations", by which any transfer is to be understood as resulting from recapitulating the specific processing operations a person learned to perform on a stimulus within a particular context on a previous occasion: to the extent that the later test involves the same operations as the earlier one, processing will be facilitated.

By Whittlesea and Jacoby's account, the direction of causation underlying semantic priming is from the probe back to the prime, the opposite of that assumed by activation theories. It assumes that processing the prime is a learning experience, like any other stimulus encounter. That experience establishes a resource for performing other, similar activities on other stimuli that are related on relevant dimensions. That explanation has been applied to long-term priming effects, including repetition priming (Scarborough, Cortese & Scarborough, 1977), form-based priming (Ruekl, 1990) and morphological priming (Bentin & Feldman, 1990). Whittlesea and Jacoby (1990) argued that it can also be applied to semantic priming.

In accord with Whittlesea and Jacoby's (1990) ideas, Becker, Moscovitch, Behrmann, and Joordens (1997) suggested that semantic priming is not observed outside the boundary conditions because the usual test tasks (naming or lexical decision) do not require extensive semantic processing (cf. Borowsky & Besner, 1993; Chumbley & Balota, 1984). By increasing the demands of the task (i.e., they used an animacy decision as the task), they were able to observe reliable semantic priming effects at up to 8 lags.

Hughes and Whittlesea (2003) modified these procedures by making the test task more challenging, but also different on every trial. For example, on prime trials, the subject would be asked to judge whether APPLE is a kind of FRUIT or MACHINE, or whether COBRA is a kind of BIRD or SNAKE. On probe trials, they could be given a primed target, such as ORANGE (a semantic associate of APPLE) and asked if it is a kind of FRUIT or JEWEL; or could be given an unprimed target such as CROW and asked if it is a kind of FRUIT or BIRD. Under these circumstances, they observed semantic priming effects of about 60–100 ms, enduring over a lag of 90 intervening questions and about a one-half hour interval. These long-term transfer effects demonstrate that semantic priming is not an inherently short-lived effect, but is so usually because of the extreme ease and non-distinctiveness of the prime and probe tasks (naming, lexical decision). Contrary to the idea of semantic priming illustrating a transient perturbation in an essentially stable system, these new observations suggest that it is a learning effect, occurring in much the same way that learning and recall or recognition occur in remembering tasks. Consistent with the data presented so far, these observations deny any strong distinction between processes conducted in "semantic" and "episodic" tasks.

Control studies revealed that these large and enduring semantic transfer effects depended both on performing a somewhat elaborate verification task on both the prime and probe trials, and that the decision for the prime and probe be the same (e.g., that the answers to both LION and TIGER both be ANIMAL). Further control studies revealed that the same size of priming effects occur not just with category verification, but also for the selection of categorical associates (e.g., PEAR – APPLE – CROW in the prime phase, and PEAR – ORANGE – COBRA in the probe phase) or of features (e.g., PEEL – APPLE – FEATHER in the prime phase, and PEEL – ORANGE – HISS in the probe phase). That is, semantic transfer was observed at three levels of abstractness: categorical membership of exemplars, association with other category exemplars, and features of particular exemplars. That might suggest to some readers that the semantic transfer observed was mediated by activation of knowledge about the category as a whole, perhaps through activation of some prototype representation of the category, giving primed access to all knowledge of the category at all levels of abstraction.

The authors tested this idea through cross-level priming, for example FRUIT – APPLE – BIRD in the prime phase and PEEL – ORANGE – HISS in the test, or alternatively PEEL – ORANGE – HISS in the prime phase and FRUIT – APPLE – BIRD in the test phase. In contradiction of the “categorical activation” hypothesis, no priming was seen in these cases. The authors concluded that, although the phenomenon occurs broadly across levels of abstraction, it occurs only when the same relationships are presented for both the prime and the probe. They thus further concluded that the phenomenon does not involve spreading activation in a semantic network, but instead reveals the importance of “overlapping operations,” an idea introduced by Paul Kolers (1973, 1976). By this principle, any transfer is to be understood as resulting from recapitulating the specific processing operations a person learned to perform on a stimulus within a particular context on a previous occasion: to the extent that the later test involves the same operations as the earlier one, processing will be facilitated.

This concept of overlapping operations is central to the “production” function of the SCAPE framework. It explains all manner of transfer effects, when critical aspects of an earlier and later experience are specifically similar and distinctive, whether those aspects are of the nominal stimulus, the context, or the task. As illustrated in the “implicit learning” section provided above, it is not even necessary for the subject to be aware of the overlapping components to gain advantage from them.

Perhaps a more subtle point that is made in the Hughes and Whittlesea study is the importance of using a number of trials; each treated as a separate instance. Thus effects are less likely to be stimulus specific. While some consumer researchers examine effects of variables of interest on a significant number of brands (e.g., Morrin & Ratneshwar, 2003), other examine effects on only a limited number of brands (e.g., Jewell & Unnava, 2003; Krishnan & Shapiro, 1996; Nedungadi, 1990). Of special interest is the article by Nedungadi (1990). He argued that (a) indirectly cueing to a brand category will produce selective effect on “retrieval” and inclusion into the consideration set, in the absence of an effect on evaluation, and (b) that indirect “priming” (i.e., prior exposure to a related brand) selectively affects only the major brand in a minor subcategory of brands. That is, repeating Subway (minor brand in minor subcategory of fast-food places) three times increases “retrieval” of Joe’s Deli (major brand in minor subcategory), however, repeating Wendy’s (minor brand in major subcategory) three times *does not* increase “retrieval” of McDonald’s (major brand in major subcategory)

A major limitation of Nedungadi’s study is that he used only a select number of brand categories. Wagner and Kronlund (2005) performed a near-replication of Nedungadi’s study, however they used 28 brand categories, and operationalized “priming” by having subjects read four brand names

(e.g., Honda, GMC) and 14 associates (e.g., tire, gas, brakes) for each brand category. Critically, they never showed any major brands (e.g., Toyota). Unlike Nedungadi, they found consistently, subjects *falsely recognized* the major brand more often than any of the minor brands (or associates). That is, when subjects read “can, drink, soda...Pepsi, Sprite, Mountain Dew,” they reported having seen Coke, but not Dr. Pepper.

In a subsequent study, they asked for subjects to report preference ratings for target brands after they had made their recognition decision. Subjects’ preference ratings of the major brands were reliably higher than preference ratings for minor brands regardless of whether they were cued by their respective lists or not. Thus, preference ratings corresponded to remembering. Taken together, these results suggest that brand primes can indirectly shape brand remembering, but *only* for major brands. Further, influences on brand choice may not be independent of brand evaluation, as suggested by Nedungadi (1990). These findings provide us with the basis for using our stimulus set to assess the relationships between consideration set inclusion, brand evaluation, and choice. We have research currently underway that explores this possibility.

INHIBITION

Repeated practice in recalling some members of a category (e.g., apple, orange, pear; apple, orange, pear, etc.), impairs later recall of other members of that class (e.g., banana, strawberry, kiwi), but not members of other classes (e.g., dog, rabbit, giraffe). This observation is termed *retrieval induced forgetting* (RIF; Anderson, Bjork, & Bjork, 1994).⁶ The notion is that repeated practice of some members of a class requires *inhibition* or suppression of unpracticed members of that category. Inhibition persists and prevents later recall of the unpracticed members. The result is that subjects are *less likely* to recall unpracticed items from practiced categories than items from non-practiced categories. Importantly, other categories are unaffected.

This idea once again assumes a network organization of memory that operates under principles of activation and inhibition. Such an inhibition account is dominant in other studies showing a decrement in performance, including studies on directed forgetting (Bjork, 1989; Bjork, Bjork, & Anderson, 1998), negative priming (e.g., Neill, 1977; Tipper, 1985; Tipper, Meegan, & Howard, 2002), and repetition blindness (Kanwisher, 1987, 1991; Kanwisher & Potter, 1990; Park & Kanwisher, 1994).

Such an inhibitory mechanism has been assumed by many investigators of consumer memory (e.g., Keller, 1991), although some use the terms “inhibition” or “suppression” and “interference” interchangeably (e.g., Burke & Srull, 1988; Jewell & Unnava, 2003; Kumar & Krishnan, 2004; Law, 2002; Unnava & Sirdeshmukh, 1994). The interference hypothesis however does not require the assumptions of a network organization. Rather, according to the interference hypothesis, performance in recalling category members will be facilitated to the extent that appropriate cues are available for accessing the traces, and will be impeded to the extent that the demands of the task are difficult. That is, while an inhibition account would predict that recall of unpracticed members are inaccessible; an interference account would predict that recall of unpracticed members are accessible, so long as the appropriate cues are provided during the test.

To demonstrate this point, Kronlund and Hughes (2005a) replicated the basic finding of RIF using eight categories.⁷ After studying all eight category lists, half of the members from four of the categories were practiced; the other four categories were not practiced. We found that subjects were less likely to recall unpracticed items from the practiced categories than from the non-practiced categories.

The stimuli however, were chosen such that they could be subcategorized by a distinctive feature (e.g., red fruits vs. non-red fruits). In a subsequent study, the practiced members from the practiced

categories were specifically grouped according to a feature (e.g., all non-red fruits were practiced). At test, we cued subjects with the feature (e.g., “Fruits that are red?”) and were able to eliminate the effect: subjects were able to report unpracticed items from practiced categories. This finding suggests that the RIF effect is due to within-category interference.

To provide further evidence that the effect is not due to inhibition, in a subsequent study (Kronlund & Hughes, 2005b), we randomly assigned subjects to groups: one group was tested using the standard RIF procedures (i.e., all eight categories: four practiced, four unpracticed), a second group performed the procedure for six categories (three practiced categories, three unpracticed), and a third group performed the procedure for only four categories (two practiced categories, two unpracticed). Assignment of categories into conditions was randomly-determined, and was re-randomized for each subject. According to inhibition accounts, repeated practice of some members of a class requires inhibition of unpracticed members of that category, but not other categories. An inhibition account would predict that the amount of RIF found should not change as a function of the number of categories used. We found that the amount of RIF *decreased* as the number of categories tested decreased, suggesting between-category interference.

The results of Kronlund and Hughes (2005a, 2005b) demonstrate that a change in the way that stimuli are construed or characterized within the task can eliminate or enhance observed transfer. This point will be further demonstrated by the “mere exposure” studies described in the subsequent section. Kronlund and Hughes’ results also highlight one final point: in contradiction of the neo-associationistic assumptions of accounts like the semantic/episodic distinction: the world does not consist of stable combinations of features that are available to be mapped into the mind of the prepared individual. Instead, consistent with the fundamental assumption of the SCAPE framework, the world consists of affordances and constraints; but is fundamentally ambiguous until the person supplies some particular organization of those features, based on past experience with similar stimuli, or the demands of the task, or the implications of the context.

THE IMPLICIT/EXPLICIT DICHOTOMY

Graf and Schacter (1985) proposed a distinction between implicit and explicit forms of memory as the fundamental dichotomy. The notion is that differential levels of consciousness are involved in performance, and that an implicit form of memory exists to account for effects of prior experience on current behavior in the absence of conscious awareness (e.g., effects observed in a priming task), whereas an explicit form of memory exists to account for behavior accompanied by conscious awareness (e.g., effects observed in a remembering task).

This dichotomy has been increasingly used as a theoretical framework by investigators of consumer memory (e.g., Krishnan & Shapiro, 1996; Lee, 2002). Lee (2002) introduced the implicit/explicit dichotomy as a means to evaluate exposure to brand names. She presented subjects with a list of brand names either in the context of a sentence (e.g., “He threw the case of Heineken in the truck of his car and drove off”) or in isolation. After completing a distractor task, half of the subjects made a memory-based choice (i.e., subjects were presented with “beer” and asked which brand they would prefer be sold in a new store opening on campus) or a stimulus-based choice (i.e., they were asked to choose among two exemplars which brand of beer to stock). When presented in a sentence, the probability of brand choice for that brand was higher for the memory-based task than for the stimulus-based task, and the reverse occurred when the brand was presented in isolation. Lee concluded that such results demonstrate that “the effects of presentation context on conceptual and perceptual priming provide clear support that the two types of implicit memory are distinct constructs of memory” (p. 447), thus further subdividing implicit memory. She suggested that implicit memory tasks are superior to explicit tasks for measuring advertising effectiveness.

Another example of the use of the implicit-explicit dichotomy is in the *mere exposure effect* (Zajonc, 1968). The mere exposure effect is the observation that when pictures of the same category (e.g., chairs) are presented in rapid serial visual presentation (RSVP) format, recognition for items shown is at chance, but pleasantness ratings for items presented previously is above chance. This difference in awareness is thought to be due to different memory systems. The indirect test of preference is thought to be mediated by implicit memory; the direct test of recognition is thought to be mediated by explicit memory (Bornstein & D'Agostino, 1994; Schacter, 1990; Seamon, et al., 1995). The same applies to preference of brand names. "Mere exposure" to an ad or brand is thought to have an effect on fluency of processing of brands, such that brand choice and consideration-set membership can be affected (Nedungadi, 1990; Shapiro, 1999), and this is thought to be mediated by some form of automatic, spreading activation between hypothetical nodes in the brain, such that prior exposure of a brand or related brand facilitates processing of the target brand during brand choice or consideration-set.

FLUENCY AND THE MERE EXPOSURE EFFECT

In the case of the mere exposure effect, fluency of processing is thought to mediate increased ratings of liking, even in the absence of conscious recollection of the target stimulus (e.g., Bonnano & Stillings, 1986). The failure of reaching above chance levels in recognition is thought to be due to ineffective encoding of the stimuli caused by the rapid presentation of the items during the study phase (e.g., Bornstein & D'Agostino, 1994). However, a puzzle arises because fluency of processing also allows one to infer from the fluency of current performance to an earlier, perhaps in some cases hypothetical, experience of the stimulus and thus to make an effective remembering decision (Jacoby, Kelley, & Dywan, 1989). In fact, recognition memory results from either of two bases, *familiarity*, governed by fluent processing (e.g., Jacoby & Dallas, 1981), which is usually associated with the earlier global encoding of the stimulus, or *recollection*, governed by a remembering of details of a stimulus, which is associated with earlier, effective encoding of detailed elements of a stimulus (e.g., Mandler, 1991; see also Joordens & Hockley, 2000). Thus a paradox emerges: why is it that subjects are capable of using fluency as a basis for preference but not for recognition?

Whittlesea and Price (2001) attempted to disambiguate why the feeling of familiarity was not powerful enough to cause recognition ratings to be above chance in any previously examined mere exposure experiment. In their study, they first replicated the basic mere exposure effect. When subjects were asked to choose which of two items they preferred, they performed above chance in a preference judgment for items shown earlier, but were at chance on recognition for those items. They then performed two more experiments, one in which subjects were asked to choose which of two items globally resembled an item shown earlier, and one in which subjects were asked to choose which of two items they preferred and to justify their decision. In the former, subjects performed above chance at recognition, probably due to the non-analytical processing that they were required to do, which allowed them to experience and use fluency in their response. In the latter, subjects were at chance at preferring the old item, likely due to the now analytical processing that they were using, which prevented them from experiencing the fluency.

This demonstration shows the importance of thinking of memory not in terms of explicit and implicit systems, each only measurable by direct and indirect tests of performance, but rather as a unitary system, that uses different strategies which depend on the stimulus, task, and context. Memory uses the same set of knowledge and skill to perform a variety of tasks, including both remembering (recognition) and non-remembering (preference) tasks, using a variety of dimensions (e.g., analytic/non-analytic, specific/general, etc.). Whittlesea and Price's focus on types of

processing used also explains mere exposure effects reported in the consumer literature (e.g., Nordhielm, 2002).

According to the separate systems account, awareness of the source of one's performance depends on the type of task one is performing, and the type of memory system (explicit or implicit) that that task accesses. In contrast, according to the SCAPE account, awareness of the source of performance is constructed through a process of generation, inference and attribution, in the same way that the performance itself is constructed. Explicit versus implicit is a description of the outcome of this process, not a description of the knowledge on which it is based or the process that controls performance and creates awareness. As illustrated in the next section, one consequence of this constructive process is that one can become aware of sources of performance that do not exist.

In the case of Lee (2002), the same applies. She highlighted the principles of elaboration and specificity. Her data reveal that the principle of TAP fully explains her data: the degree to which resources used for the given test match the resources used earlier (e.g., a memory-based task would rely on skills needed for generation, elaboration, and deeper processing—the same skills used when processing a brand in the context of a meaningful sentence as opposed to in isolation). There are yet other examples of dissociations that can be explained with the same principle (e.g., Janiszewski, 1993; Krishnan, 1999; Krishnan & Shapiro, 1996). Thus Lee's (2002) demonstration showed two dissociated *strategies*, not evidence for separate constructs of memory. This is often the case with research thought to provide test contexts which are believed to selectively tap into explicit and implicit memory systems. Those test contexts simply foster subjects in adopting different strategies which either facilitate or preclude them from experiencing priming. We submit that this is an important consideration for consumer researchers, who may simply be creating contexts which facilitate different processing strategies.

FLUENCY AND RECOGNITION

When subjects are able to experience fluency of processing, another problem arises when trying to interpret the meaning of the observation. Is it the absolute fluency of processing that is responsible for observable changes in performance? Or is it that subjects are responding to some type of perceived relative fluency? Said another way, are subjects able to form and use expectations about how fluent something ought to be? And then only if this expectation is met or exceeded respond a certain way?

The idea of fluency as a basis for recognition decisions was originally investigated by Jacoby and Dallas (1981). They performed a recognition experiment using low frequency (e.g., JANITOR) and high frequency (e.g., TABLE) words. At test, before making their recognition decision, subjects were required to make a tachistoscopic identification of each word; identification was used as an index of fluency of processing. Jacoby and Dallas observed that high-frequency words were processed more fluently than were low-frequency words. More importantly, prior experience enhanced the fluency of processing for the low-frequency words *more than* that of the high-frequency words. Further, they found that low-frequency words that were studied were more likely to be claimed "old" than high-frequency words which had been studied. Jacoby and Dallas suggested that subjects appeared to be impressed not by the absolute fluency of processing of a target item, but rather by the *relative* fluency of processing: subjects were impressed by the deviation between actual and expected fluency. Thus, relative fluency led to a feeling of familiarity.

Since Jacoby and Dallas' (1981) influential study, many investigators have observed similar effects of changes in fluency on recognition claims (e.g., Dewhurst & Hitch, 1997; Drummey & Newcombe, 1995; Higham & Vokey, 2000; Johnston, Hawley, & Elliott, 1991; Lindsay & Kelley,

1996; Luo, 1993; Masson & Macleod, 1996; Mayes & Gooding, 1997; Mulligan & Hirshman, 1995; Polson, Grabavac, & Parsons, 1997; Rajaram, 1993; Seamon, Luo, & Schwartz, 2002; Snodgrass, Hirshman, & Fan, 1996; Stark & McClelland, 2000; Ste-Marie, 1996; Verfaellie & Treadwell, 1993; Wippich & Mecklenbraeuer, 1994; Whittlesea & Leboe, 2000). The fluency-attribution idea has also been applied to understanding consumer behavior (e.g., Janiszewski, 1993; Janiszewski & Meyvis, 2001; Lee, 2002; Lee & Labroo, 2004).

There are two major problems with the above-mentioned studies as well as numerous other studies investigating fluency. First, unlike the procedure used by Jacoby and Dallas, the fluency manipulation in these studies was experimental: fluency was enhanced by some type of manipulation. The major disadvantage is that this minor procedural difference creates a confound: both absolute and relative fluency are enhanced, simultaneously, thus it is unclear which type of fluency is operating, and many investigators claim that it is the absolute type. Second, it seems illogical that the feeling of familiarity is created from absolute speed of processing. One's child, partner, friend, or even dog, although very fluently processed, never cause a feeling of "have I seen you before?" (Whittlesea & Williams, 1998).

This notion was investigated by Whittlesea and Williams (1998). They presented subjects with well-known words (e.g., TABLE), difficult to pronounce nonwords (e.g., LICTPUB) and easy to pronounce nonwords which were created from real words by changing one or more letters to create a nonword (e.g., HENSION). Each type of stimulus was studied for a memory test. During the test phase, subjects first named each word (to get an index of processing fluency) and then made a recognition decision on old and new stimuli of each category. The words (e.g., TABLE) were processed the most fluently (827ms), but were *not* associated with the most claims of "old." The HENSION items on the other hand, although processed less fluently than the words (988ms), produced the most false alarms (37% vs. 16% for the words).

Whittlesea and Williams (1998) reasoned that when reading the easy to pronounce nonwords surprise resulted from an unknown source that was wrongly attributed to the past. For example, when reading HENSION, subjects expected a meaningful word, but it was a nonword. It was the surprise associated with the mismatch between expectation and outcome which led to the feeling of familiarity. Said another way, the HENSION items were processed more fluently than could be expected for a nonword. This created the perception of discrepancy, leading to a feeling of familiarity. This study was replicated by Menon and Raghuram (2003) using the accessibility/ease of retrieval framework (see also Huber, 2004).

In this case, absolute fluency and relative fluency were not confounded, and though the regular words were processed more fluently than either of the nonwords, expected and actual fluency were matched. Whittlesea and Williams (2001a) proposed the *discrepancy-attribution hypothesis* which states that when there is a mismatch between expected and actual performance on a given stimulus in a given context (in this case, the test context), the perceived discrepancy is consciously experienced as the feeling of familiarity, and unconsciously attributed to a prior experience of that stimulus.

Whittlesea and Williams (2001a, 2001b) attempted to create and examine the perception of discrepancy using a different paradigm which consisted of probe items following a predictive sentence stem and a pause (e.g., "The stormy seas tossed the...BOAT"). Using this procedure during a test phase (targets in isolation during the study phase), subjects were more likely to claim "old" for probes following a predictive stem and pause as opposed to a predictive stem and no pause. In this case, the predictive stem was thought to create an expectation, the pause uncertainty, and the terminal word a surprising validation, similar to what occurs when waiting for the other shoe to drop.

When the subjects tried to identify the source of the surprise, their decision was based on the salient aspects of the stimulus (the semantic relationship of the stem and target), given the task and context. While subjects were focusing on the salient aspect of the task, they experienced the perception of discrepancy upon seeing the terminal probe. Knowing that they were in a recognition experiment, subjects unconsciously attributed the surprise to a prior experience of the target word, consciously experiencing the feeling of familiarity.

The perception of discrepancy occurs when outcomes either violate or validate expectations in a surprising way. Note that in the case of HENSION, a surprising violation occurred. Often this surprise occurs because the expectation is a constrained, indefinite one, so that the relationship between expectation and outcome is ambiguous (Whittlesea, 2002b). In support of this, Whittlesea and Williams (2001b) did not find increased false alarms for probes following a predictive stem and pause when subjects had to make recognition decisions on (a) probes that the subject generated as a completion to the stem, (b) probes following completely predictable stems (e.g., row, row, row, your GOAT), or (c) probes following completely predictable stems that are violated (e.g., row, row, row, your SHEEP).

This is not to say that absolute fluency, when unconfounded with relative fluency, is not associated with claims of familiarity. There are some cases in which people have been found to use absolute fluency to make judgments about self-alertness (Shimizu, Renaud & Whittlesea, 2006), aesthetic merit (Winkielman, Schwarz, Reber, & Fazendeiro, 2003), and nonwords (Whittlesea & Leboe, 2003).

Taken together, the evidence seems to suggest that people will only use the absolute fluency of performance to make remembering decisions when that is the only possible source of information, that is, when they cannot easily create and use expectations about the normative fluency for the target item. The evidence also seems to suggest that people invariably use the perception of discrepancy rather than absolute fluency for most decisions related to the feeling of familiarity.

A case in the consumer behavior literature whereby it is not clear whether subjects are responding to absolute or relative fluency was the study by Lee and Labroo (2004). They used Whittlesea's (1993) sentence stem paradigm to create conceptually fluent processing of words. They presented words in the context of predictive (e.g., the woman soaked the white sweater in some cold *water*) or non-predictive (e.g., the woman looked out of the window and saw the *water*) sentence stems. Another manipulation they used was presenting the target word as the same (*water*), related (*drink*), or unrelated word (*house*) immediately following the sentence. It was expected that the productiveness of the stem and the similarity of the target to the last word in the sentence that would both effect conceptual fluency, and that the repetition status would effect perceptual fluency. Results revealed that pleasantness ratings were higher for words in the predictive versus the non-predictive context and the related versus unrelated target words. This finding was the basis for later examining, and replicating, these effects with consumer products. It may be the relative fluency that is the basis of changes in attitudes or changes in pleasantness ratings in Lee and Labroo's (2004) study.

REMEMBERING

The above-chance pleasantness and recognition judgments observed in the "mere exposure" experiments reported earlier likely occurred because prior exposure caused the old member of test pairs to be processed with greater fluency than the novel member (i.e., repetition priming), at least when subjects performed nonanalytically. That is, these subjects appear to have used a simple decision heuristic such as "if fluent then old/pleasant" (cf., Jacoby & Whitehouse, 1989). However, the evaluation process that leads to a subjective reaction can be considerably more complex than that. Whittlesea and his colleagues (e.g., Kronlund & Whittlesea, 2005; Kronlund & Whittlesea, 2006;

Whittlesea, 2002b, 2004; Whittlesea & Leboe, 2003; Whittlesea & Williams, 2001a, 2001b) investigated the source of the feeling of familiarity. They concluded that people chronically examine their cognitive and perceptual processing at a variety of levels, attempting to integrate various aspects of that processing with other aspects (the “evaluation” function of mind described earlier). In doing so, they come to one of four primitive conclusions, or perceptions, about their current processing: *coherence* (well-formedness), *incongruity* (wrongness), *discrepancy* (strangeness), or *integrality* (predictability or unity). These primitive perceptions are not usually experienced consciously. Instead, they are further interpreted under some intuitive theory of cause and effect, and within the implications of salient aspects of the task, stimulus and context; this extended interpretation gives rise to some specific subjective reaction, such as a feeling of pleasantness, interest, or familiarity.

The perception of coherence occurs when all aspects of the current experience seem to fit well with others; the chief reaction to that perception is to accept the current processing event and move on. The perception of incongruity occurs when some aspect of current processing is clearly inconsistent with others, for example when a speech error is made or when stimulus elements conflict semantically or at some other level (e.g., on reading “The hunter sat quietly on the dog”). The chief reaction to the perception of incongruity is to stop processing the inflow of environmental stimuli and to focus on the source of the incongruity, resulting in error correction.

In contrast, the latter two perceptions can sponsor strong feelings of familiarity or remembering. The perception of discrepancy appears to occur when an indefinite expectation is surprisingly validated (Whittlesea & Williams, 2001b). The perception of discrepancy does not always cause illusory feelings of remembering, however; the errors committed by subjects experiencing this perception simply reveal the common mechanism whereby such feelings are aroused (i.e., the feelings contribute as much to hits as to false alarms); perception is probably primarily responsible for weak or powerful feelings of familiarity that occur without actually recalling the target event (i.e., without becoming aware of the distinctive context of the earlier event). Finally, the perception of integrality sponsors more extensive and specific claims of remembering. That perception, however, appears to occur when a *definite expectation* is validated by a consistent outcome (Kronlund & Whittlesea, 2006; Whittlesea, 2002a).

The conclusions that remembering occurs indirectly, through adopting an attitude to a production rather than directly through retrieval, and that the feelings of remembering that produce this attitude occur through a heuristic process of evaluation and inference, may seem extreme given the limited evidence presented here. However, both patterns of effects have been replicated repeatedly and subjected to all manner of convergent tests (cf. Kronlund, 2006; Kronlund & Whittlesea, 2006; Whittlesea & Williams, 1998, 2000; Leboe & Whittlesea, 2002; Whittlesea, 2002b, 2004). They suggest two quite different routes to a feeling of remembering, one based on surprise caused by the validation of an indefinite expectation aroused on the fly, the other based on the validation of a definite expectation laid down by prior specific experience. However, they share the same basic principles: in chronically evaluating their productions, people attempt to make what sense they can of the significance of apparent fit or lack of fit of the components of the current experience. They make inferences about the causes of the primitive perceptions aroused by different experiences, and make attributions to plausible sources.

CONCLUSIONS AND FUTURE DIRECTIONS

We have presented a small part of the data on which the SCAPE framework is based. However, the variety of evidence presented demonstrates that that account can make predictions about performance in both “episodic” and “semantic” tasks, through a single set of underlying principles: construction, with its corollary sub-functions of production and evaluation. This evidence is at

least challenging for proponents of separate-systems accounts: it requires them to provide functional explanations at a deeper level than “there are two kinds of knowledge, and therefore two memory systems specialized to deal with them.”

In re-evaluating their functional analysis, we would hope that researchers will listen to the wisdom of the user of memory. Such sensible statements as “I used to *know* his name, but I can’t *remember* it now” reveal clearly some of the functional significance of such categories to the user: “know” means easy and fluent use of the past, with emphasis on *use* of the knowledge for some other purpose, rather than its accessibility; whereas “remember” means reflective use of the past, with focus on the act of making contact with the past. We submit that such functional analysis is essential, and cannot be replaced by neuropsychological investigations of correspondences between gross tasks and areas of brain activation. For example, Elliot and Dolan (1998) conducted a standard “mere exposure” study, and obtained the usual behavioral results (preference judgments biased toward old items, but recognition at chance). They also recorded brain activity via fMRI. They observed that the preference task was associated with right lateral prefrontal activity, whereas recognition was associated with left frontopolar and parietal activity. They concluded that that observation gave physiological support to the explicit/implicit memory dichotomy, indicating the anatomical distinctness of the subsystems responsible for the two behaviors. However, given the evidence above that the usual results of such studies come about through encouraging analytic versus non-analytic processing rather than two separate memory systems, the meaning of the fMRI data becomes much more difficult to interpret.

Our major point is thus simply this: one cannot *assume* that one knows the functions of memory; and no amount of physiological correlations will corroborate those assumptions. Instead, a more thorough task analysis is required, using convergent operations and broad examinations of dissociations and correspondences across widely different kinds of task.

Concepts of memory are continually molded and shaped by empirical findings and researchers’ interpretations of those findings. Although the fundamental concepts of memory tend to change very slowly, conceptual changes do nonetheless occur. Almost no attention has been paid, however, to ensuring that we understand the similarities and differences among the terms, concepts, and assumptions related to memory. One frequent source of confusion lies in the use of one and the same term (e.g., priming) to refer to different concepts. Another common source of confusion is the use of different terms to refer to the same construct (e.g., fluency, accessibility, ease of retrieval⁸). It is our position that the lack of an effort by researchers to consider and weigh the conceptual similarities and differences among memory theories and studies has hampered our understanding of consumer memory. In this chapter, we elucidate some of the problems with the contemporary memory theories and the studies that implicitly or explicitly build on those theories. By doing so, we seek to encourage consumer researchers to place greater emphasis on conceptual clarity that will lead to meaningful advances in our understanding about consumer memory.

NOTES

1. A notable exception is the constructive view of consumer decision making posited by Bettman, Luce, and Payne (1998).
2. Note similarities between assumptions of SCAPE and Schwarz (2004), although see Huber (2004).
3. Readers interested in a critique of the procedural/declarative dichotomy may wish to examine Whittlesea (2002a).
4. Although distinct, the concept of activation is often used interchangeably with conceptual fluency (e.g., Lee, 2002; Lee & Labroo, 2004; Shapiro, 1999; see section on Fluency and Recognition below).
5. The term *priming* was originally used by Meyer & Schvaneveldt (1971) to describe facilitation in lexical decision of a word when that word is preceded by a meaningfully related word. The proposed mechanism for the effect at the time was “forward acting” spreading activation. We find that today, 35 years

later, people confuse mechanism with observation: facilitation in processing, however observed, can result from backward-acting TAP, through the use of matched resources, etc. (see the discussion of Whittlesea & Jacoby, 1990, and Hughes & Whittlesea, 2003, below).

6. Although this effect, and the notion of inhibition, has spurred further investigation by many psychologists since 1994, the effect itself, as well as the mechanism of inhibition, was actually discussed in 1985, by Alba and Chattopadhyay. They argued that both the retrieval practice, and the act of recall, cause inhibition. Their paper was not cited in 1994 by Anderson et al., or by any investigators who have cited Anderson's work. Interestingly, those who have cited Alba and Chattopadhyay's (1985) article since 1994 appear to not have cited the work of Anderson et al. (1994).
7. For the studies described here, Kronlund and Hughes (2005) used categories such as animals, fish, etc., however in other studies, they replicated their basic findings with brand name categories such as soda and shampoo.
8. A notable exception is Schwarz (2004) who distinguishes between fluency and accessibility and provides many consumer psychological examples. He also distinguishes between accessible content and accessibility experiences. Consistent with the implications of the SCAPE model, Schwarz (2004) emphasizes the importance of implicit theories for linking experiences and inferences.

Consumer Learning and Expertise

J. WESLEY HUTCHINSON

University of Pennsylvania

ERIC M. EISENSTEIN

Cornell University

Consumer learning has been a central construct in models of consumer behavior since at least the 1960s (e.g., Howard & Sheth, 1969; Massy, Montgomery & Morrison, 1970). Research on consumer knowledge and expertise is more recent (e.g., Bettman & Park, 1980; Brucks, 1985; Alba & Hutchinson, 1987). In cognitive psychology, the topics of learning and expertise are more or less separate domains, or perhaps more accurately, expertise is a subfield that focuses on the highest levels of learning, where learning has occurred naturally over many years rather than in the laboratory as the result of experimental procedures (e.g., Chi, Glaser, & Farr, 1988; Shanteau, 1992). In consumer research, the topics have been more closely related and generally involve comparisons of more knowledgeable and less knowledgeable consumers without requiring that the more knowledgeable consumers be experts in the sense of representing the highest attainable levels of knowledge (e.g., grand masters in chess, professional judges of agricultural products, medical doctors, meteorologists, etc.). This focus on “relative” rather than “absolute” expertise is natural because many (arguably most) important problems in consumer behavior involve the very earliest stages of naturalistic learning (e.g., the adoption of innovations, transitions from trial to repeat purchases, differences between light and heavy users, etc.). Thus, in this chapter we emphasize the integration of learning and expertise and focus on the effects of relative differences in consumer knowledge across individuals.¹

THE “PERFECT WORLD” PERSPECTIVE

To structure our review of research on consumer learning and expertise, it is useful to note a perspective that is seldom explicitly endorsed or rejected, but is lurking behind the scenes in the literature on consumer knowledge. In the normal course of everyday life, people have many experiences that involve products (i.e., goods and services), and they become increasingly familiar with those products. Also, over time people learn from these experiences and gain true expertise in a variety of product domains. Following Alba and Hutchinson (1987), we use the term *familiarity* to refer to the accumulated level of product-related experiences and *expertise* to refer to the ability to perform product-related tasks successfully. We will refer to the general hypothesis that increased familiarity leads to increases in expertise as *learning from experience* (H1). Also, it seems reasonable that as expertise increases, people become better and more efficient in their roles as consumers. We will

refer to this general hypothesis as *improved consumer welfare* (H2). As will become evident as we proceed, these hypotheses are not always supported, and sometimes opposite results obtain (i.e., increased familiarity leads to less expertise or increased expertise leads to lower welfare), but most people would agree that the world would be a better place if it worked according to H1 and H2. Hence, we have dubbed this pair of hypotheses the “perfect world” perspective.

Independent of whether the perfect world perspective is valid or not, one result of research in this area has been to show that the key constructs—product familiarity, consumer expertise, and consumer welfare—are multidimensional in nature (see Figure 4.1).

Product familiarity can arise from a wide variety of experiences, including information search, repeated decision making, repeated product usage and consumption, and deliberate practice. Each of these types of experience has been found to increase expertise in some cases, but not in others. However, high levels of expertise are seldom obtained without successful information search, or without clear and immediate feedback about the outcomes of decisions, usage, and consumption. In consumer domains that include competitive performance or creative expression, deliberate practice is often essential.

Similarly, there are a number of benefits that could arise from product familiarity through the development of consumer expertise. First, consumers could become more completely and perfectly informed because expertise allows consumers to comprehend, retain, recall, and infer more information with lower levels of error. Second, consumers could make more optimal decisions because they learn more successful strategies, rely less on simple heuristics, are able to reason further into the future and conform more to traditional conceptualizations of “rational,” utility-maximizing behavior. Third, consumers could incur lower costs of information search, product usage, and consumption because they become faster and better at these activities or because they learn new, more efficient strategies and behaviors. These costs would include time, money, and mental and physical

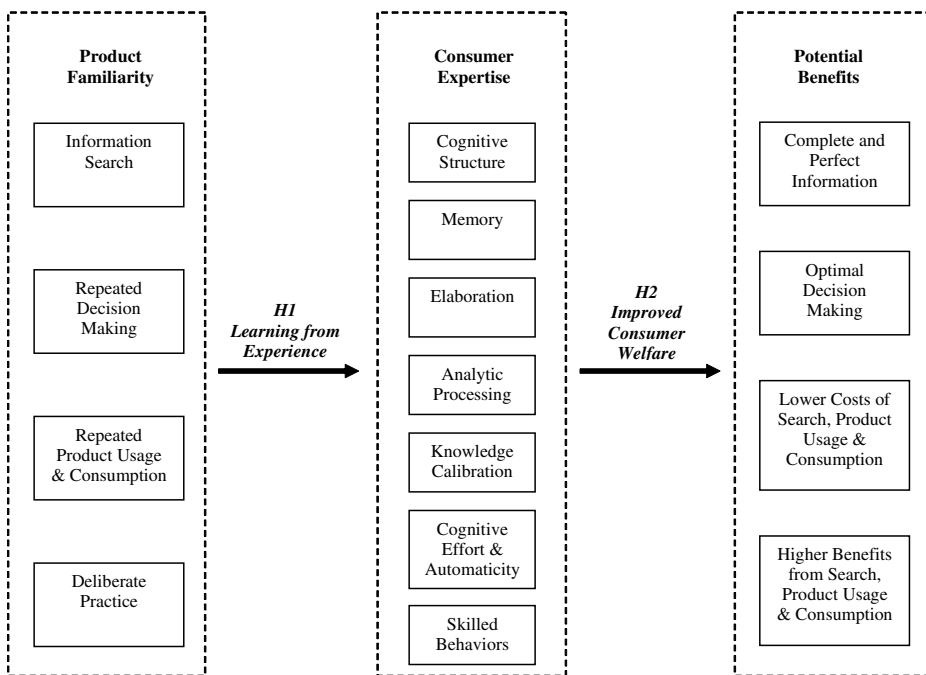

Figure 4.1 The “perfect world” perspective

effort. Finally, consumers could obtain more or better outcomes from information search, product usage, and consumption because the ultimate utilitarian and hedonic results of these activities are produced in part by consumers themselves, and expertise could create more effective production functions.

The multidimensionality of consumer expertise has been frequently noted (Alba & Hutchinson, 1987, 2000; Brucks, 1985). In the remainder of this section, we will specifically consider changes resulting from product familiarity in cognitive structure, memory, elaboration, analytic processing, knowledge calibration, cognitive effort/automaticity, and skilled behaviors, and the benefits that arise from these changes. For each dimension, we will summarize the status of learning from experience (H1) and improved consumer welfare (H2). Our discussions will highlight what we see as key results and ongoing issues and will refer readers to more comprehensive treatments of the topics. After this overview, we will continue assessing the perfect world perspective as we review theory and method in the area of consumer learning and expertise.

COGNITIVE STRUCTURE

Cognitive structure refers to the way in which factual knowledge is organized in memory. The most common forms of cognitive structures studied in consumer research are naturally occurring, taxonomic categories because the mappings onto the marketing concepts of product categories, brand families, and market niches are fairly direct. Several stylized facts from cognitive psychology are commonly adopted. First, most product categories exhibit the characteristics of basic level categories (e.g., objects are named at this level and processing is faster to identify objects as belonging to a basic level; Rosch, Mervis, Gray, Johnson, & Boyes-Braem, 1976). The central claim about basic level categories is that within-category similarity and between-category dissimilarity are maximized at this level. It is easy to see how market forces make product categories the basic level insofar as product categories are defined as collections of substitutes that compete with each other to fulfill the same consumer needs. Moreover, as expertise increases, knowledge about subordinate categories increases and information at this level is processed as efficiently as (but not more efficiently than) at the basic level (Johnson & Mervis, 1997). Second, product categories exhibit a graded structure that can be indexed by measures of typicality (Medin & Smith, 1984; Rosch & Mervis, 1975). A central issue from the perspective of consumer research is the extent to which the most typical products are also the best products (in general or for specific consumers). Third, the ad hoc and goal-derived categories that consumers often use in shopping (e.g., things to buy for a camping trip, my favorite restaurants, etc.) also exhibit graded structure (Barsalou, 1985).

Several researchers have confirmed that as product familiarity increases, especially from non-user to user of a product, cognitive structure is acquired (e.g., Hutchinson, Raman, & Mantrala, 1994; Nedungadi & Hutchinson, 1985). Mitchell and Dacin (1996) provide a particularly thorough analysis of the cognitive structures found for motorcycles. They factor analyzed 10 measures related to product familiarity and expertise and found that subjective and objective measures of knowledge loaded on the same factor; however, number owned and magazines read formed a second factor and number owned by friends formed a third. In general, their results confirm the perfect world perspective, but there are some cautionary notes. Self-rated familiarity loaded on the same factor as measures of subjective and objective knowledge, supporting learning from experience (H1). However, the independence of number owned and magazines read (which clearly indexes the number of product-related experiences) from the knowledge measures does not support H1, or at least suggests that mere ownership does not lead to knowledge. Moreover, while the knowledge measures were strongly related to measures of the organization of knowledge, ownership was only

weakly related, at best. Also, a separate experimental session assessed choices among hypothetical motorcycles for which there were objectively correct answers. The knowledge factor was strongly related to correct choices and correct reasons for the choices, supporting improved consumer welfare (H2). However, ownership was not predictive of choice, further weakening the simple view of familiarity leading to expertise leading to better decisions. These results suggest that not all types of product experiences increase learning and expertise. Interestingly, ownership of motorcycles by friends was also highly predictive of choice quality. This suggests a social dimension to consumer expertise that has not been explored in detail.

MEMORY

The hallmark of expertise in all domains is greater memory for domain facts. The classic studies of chess experts showed that grand masters could remember game configurations much better than novices, but only for configurations that were possible in real games (Chase & Simon, 1973). Memory for random configurations was the same for experts and novices. Similar results have been obtained in a wide variety of fields (see Vincente & Wang, 1998, for a discussion of theories that account for expert recall superiority). While little of this research has been called consumer research, many (arguably most) of the domains involve consumer markets (mainly for entertainment of various sorts) that become professions at the highest levels of expertise. Games (chess, bridge, and go), sports (baseball, basketball, football, figure skating, and field hockey), computer programming, and even medical diagnosis exhibit this type of continuum and have empirical evidence for expert recall superiority. Superior memory has also been found in explicitly consumer-oriented research (Mitchell & Dacin, 1996). Memory superiority, almost by definition, leads to more completely and perfectly informed consumers, and in that sense these results support both learning from experience (H1) and improved consumer welfare (H2).

In addition to greater recall, the cognitive structures that are acquired influence the recall of brands and attributes, which ones are recalled and in what order (Hutchinson, Raman, & Mantrala, 1994; Mitchell & Dacin, 1996; Nedungadi, Chattopadhyay, & Muthukrishnan, 2001; Ratneshwar, Peckman, & Shocker, 1996; Ratneshwar & Shocker, 1991). Cowley and Mitchell (2003) found that when novices were exposed to product information in the context of a specific usage situation, they could not reorganize that information in memory and successfully recall products appropriate for a different usage situation. Expert consumers were able to retain more information and better recall information that was appropriate for a new situation. Cowley and Janus (2004) found that high product familiarity consumers had better memory for a product experience and were more resistant to the biasing effects of misleading advertisements about that experience than were low familiarity consumers. Thus, in addition to information being more complete and perfect, there is evidence that decisions will be better (see also Mitchell & Dacin, 1996), supporting the perfect world perspective. In contrast, Wood and Lynch (2000) found that, compared to novices, experts were less likely to encode and remember new product information that made older information obsolete. However, experts did learn better than novices if they were cued that their knowledge might be out of date or if they were given incentives to carefully attend to all information about the new product.

ELABORATION

In addition to better organization and memory for information acquired directly from product experiences, experts sometimes exhibit higher levels of reasoning and problem solving in their domains of expertise. Alba and Hutchinson (1987) referred to these abilities as elaboration (i.e.,

new knowledge that is internally generated from old knowledge). Arguably the most frequent and important type of elaboration for consumers is the ability to infer the ultimate benefits and costs of a product based on its objective features and technical specifications and use these inferences to solve the problem of satisfying specific needs. For example, expert consumers in the domain of computer products can accurately assess the price, size, weight, CPU, RAM, cache, and I/O ports of various laptops, and choose the machine that best suits their need for out-of-office computing. Novices are less able to engage in this type of elaboration. However, novices are more likely to elaborate by simplification (e.g., many technical features are interpreted as implying performance superiority, regardless of the match between those features and their specific needs).

Evidence for accurate feature-to-benefit inferences by expert consumers and increased simplification by novices can be found in the results of an extensive experiment on mass customization conducted by Dellaert and Stremersch (2005). In this experiment a probability sample of consumers shopped for hypothetical computers using configurations of mass customization that varied in extent of customization, heterogeneity in levels of product attributes, pricing format, and presence and type of default option. These factors created large differences in the degree of success consumers had in constructing their most preferred computer (as measured by the rated utility of the final product design) and the amount of complexity they perceived in the customization process. Importantly, expertise was shown to reduce perceived complexity, increase product utility, and reduce the negative effect of complexity on product utility. These results are also supportive of the perfect world hypothesis.

ANALYTIC PROCESSING

A number of researchers in different areas of cognitive psychology have argued that there are two fundamentally different types of information processing and decision making (e.g., Hammond & Brehmer, 1973; Jacoby & Brooks, 1984; Slovic, 1996). One corresponds fairly closely to normative, logical reasoning. It is analytic and rule-based. A central characteristic of this type of thought is identifying and using only the information that is relevant and diagnostic, ignoring other information that may be salient but irrelevant. The second is associative, similarity-based, intuitive, and holistic in the sense that all salient information is integrated in some way to form an overall judgment or choose among options. Because this second type has been given so many different names and definitions, we will simply refer to it as non-analytic processing. In consumer research, this difference has been related to situational factors. Hutchinson and Alba (1991) found that intentional learning (e.g., deliberately trying to understand the product attributes that influence price) increased the likelihood of analytic information processing; however, incidental learning (e.g., learning about price when one's explicit goal is forming overall preferences), complexity, and memory load were all found to increase the likelihood of non-analytic processing factors. Importantly, several researchers have reported evidence that experts are more likely to engage in analytic processing than are novices (Alba & Hutchinson, 1987; Dillon, Madden, Kirmani, & Mukherjee, 2001; Spence & Brucks, 1997). Dillon et al. developed a psychometrically sophisticated model of brand ratings and found that the ratings of high experience consumers were more influenced by brand specific attributes and less influenced by general brand impressions than were the ratings of low experience consumers. Spence and Brucks compared professional appraisers (experts) to undergraduates (novices) in a task that required participants to estimate the market value of houses based on multi-attribute descriptions. They found that experts used fewer but more diagnostic attributes compared to novices. Both of these results are consistent with the hypothesis that processing shifts from holistic to analytic as product familiarity increases (i.e., H1, learning from experience).

KNOWLEDGE CALIBRATION

Knowledge calibration is the degree to which consumers accurately assess their knowledge about products and markets.² Typically, calibration is assessed by comparing confidence with accuracy (via a variety of methods which are discussed later). If people are high in confidence when their knowledge is accurate and low in confidence when it is errorful, then they are well-calibrated. Unfortunately, most research in marketing and psychology supports the stylized fact that people are overconfident (Alba & Hutchinson, 2000; however, see Juslin, Winman, & Olsson, 2000). They think they know more than they actually do.

Is overconfidence a bad thing? Generally speaking, the answer is yes, but there are exceptions (see Alba & Hutchinson, 2000). One obvious problem with consumer overconfidence about their level of knowledge, is that it is likely to lead to reduced information search and inattention to available information (consistent with the results of Wood & Lynch, 2002, which were discussed earlier). Also, confidence often exerts a direct influence on judgment and choice. If a consumer is overconfident that their knowledge is valid they will not appropriately factor their uncertainty into their decisions. For example, assume that a consumer is faced with a choice between Brands X and Y and believes that Brand X was rated higher than Y by *Consumer Reports*. Further assume that X is priced higher than Y, but the consumer is very confident that her belief is correct and therefore chooses X. To quantify these concepts, let's say that "very confident" means she believes her memory for what she reads in *Consumer Reports* is correct 95% of the time, the value to her for being rated higher is \$10, and (to simplify things) there are no ties in the ratings. If she is perfectly calibrated, then the expected value of choosing X is $.95 \times \$10 + .05 \times (\$0) = \$9.50$. Thus, she should be willing to pay up to \$9.50 more for Brand X. However, if she is overconfident about her beliefs and her memory is correct only 75% of the time, then the expected value of choosing X is only $.75 \times \$10 + .25 \times (\$0) = \$7.50$. If the price difference is between \$7.50 and \$9.50, then she will have chosen X when she should have chosen Y. This example shows that the overconfidence reduces consumer welfare when degree of confidence is a valid input for a decision, as is true for most decisions that require the valuation of all considered options. Some decisions, however, do not require such valuations. For example, if X and Y were priced the same, our hypothetical consumer should choose whichever brand is more likely to have been rated higher, and it does not matter whether the likelihood is 95% or 75% or even 55%. Any likelihood over 50% means X should be chosen over Y. In some cases, when valuation is not required, overconfidence may even be helpful if it leads to faster decisions or allows the consumer to worry less. Also, overconfidence may make consumers more resistant to misleading advertising and other persuasive marketing actions (e.g., see Bearden, Hardesty, & Rose, 2001; Obermiller & Spangenberg, 1998). Overall, however, we think such situations are rare, and we should regard miscalibration (i.e., over- or underconfidence) as lowering consumer welfare. The key question then is whether or not expertise increases calibration. If it does, then H2 of the perfect world perspective holds. If it does not, or if it instead increases overconfidence, then we have the somewhat ironic outcome that even though consumers learn from experience (H1), they are worse off as a result. Unfortunately, the evidence is mixed.

Classic studies of calibration require subjects to provide numerical estimates of the probability that each response they give is correct. Most studies have found domain experts to be as poorly calibrated as novices (Lichtenstein, Fischhoff, & Phillips, 1982; Shanteau & Stewart, 1992). These results have been found for the domains of medicine, law, psychology, sports, and among undergraduates (assumed to be more expert in their major than other areas). The major exceptions have been the high level of calibration of professional meteorologists and world-class bridge players, leading some to speculate that large numbers of repetitions with immediate outcome feedback is necessary for

calibration to be improved by experience; however, Koehler, Brenner, and Griffin (2002) provide a compelling, model-based alternative explanation. Interestingly, in contrast to the voluminous evidence of the poor calibration of physicians regarding a wide variety of medical events compared yoked physicians and their patients for predictions of surviving cancer. The physicians were well-calibrated, but patients were overconfident. It should be noted that in these studies, experts are often more accurate than novice even though they are equally overconfident. This suggests that learning from experience (H1) occurs, but experience is building confidence in that learning at an excessive rate.

A similar conclusion is suggested by Cowley (2004), who examined memory for product information and its subsequent effects on choice. She found that isolated brand evaluations improved both accuracy and confidence compared to brand comparisons. However, consumer knowledge of the product domain only affected confidence. Importantly, she also showed that confidence was a much stronger predictor of choice than was accuracy. Also, Muthukrishnan (1995) found that repeated product experience (that was devoid of new information by design) increased both decision confidence and an incumbent bias that resulted in increased choice of an objectively inferior product. Finally, we note that researchers have seldom examined confidence as a predictor of consumer preferences, but when they have strong effects have been observed (e.g., Brinol, Petty, & Tormala, 2004; Huang & Hutchinson, 2007; Petty, Brinol, & Tormala, 2002; see also Hutchinson & Alba, 1991).

Thus far, overconfidence seems to be a “necessary evil” that accompanies expertise, or at a minimum, expertise does little to reduce the overconfidence observed in most situations. Perhaps the most encouraging exceptions to this conclusion are the results of Sanbonmatsu, Kardes, and Herr (1992), who found that high levels of prior knowledge allowed subjects to spontaneously detect that important product information was missing, and appropriately lower both brand evaluations and decision confidence. Subjects with low and moderate levels of knowledge exhibited biases created by missing information. From a public policy perspective, we might be tempted to conclude that benefits of expertise outweigh the costs with respect to calibration (supporting H2) because it sometimes reduces overconfidence and the biases it creates and even when confidence increases more rapidly than learning this makes consumer more self-assured about their preferences and more resistant to attempts by marketers to mislead and persuade. However, the dissociation of confidence from learning as product experience increases seems to us to be a cause for concern. This concern is probably greatest in the area of information search because overconfidence seems likely to slow the dissemination of new information and this effect will be magnified to the extent that novice consumers rely on identified expert consumers as a major source of their information.

COGNITIVE EFFORT, AUTOMATICITY, AND SKILLED BEHAVIOR

Although the definitions and theoretical explanations of automaticity vary across authors and domains of research (Bargh, 1994; Hasher & Zacks, 1979, 1984; Shiffrin & Schneider, 1977; Logan 1988, 2002), the term is generally applied to any mental process that (1) occurs in response to a specific internal or external event, (2) with little or no awareness or intentional control, and (3) requires little or no cognitive resources. Automatic processes also occur much more rapidly than similar non-automatic processes (i.e., responses to the same stimuli with the same goal that are conscious, effortful and intentionally controlled), and are unaffected by concurrent tasks that require cognitive resources. The types of process that are or can become automatic include associative recall, recognition, classification, rule learning, frequency counting, and a wide variety of verbal, quantitative, and motor skills. Almost all of these play a role in some aspect of consumer behavior (e.g.,

Alba & Hutchinson, 1987; Fitzsimons et al., 2002). Importantly for our present purpose, automatic processes are either “hard wired” (e.g., orienting responses, automatic frequency counting, etc.) or require extensive repetition of the same stimuli and responses. Thus, many processes that are conscious, effortful, and intentionally controlled for novices, are automatic for experts. Although there is considerable debate about the precise mechanisms that underlie the acquisition of automatic processes, most researchers agree that (1) repetition of any behavior leads to speedup and a reduction of cognitive effort almost immediately, and (2) after many repetitions there is a qualitative change from a controlled to an automatic process. Thus, the vast amount of research on cognitive effort and automaticity supports learning from experience (H1). Support for improved consumer welfare (H2) is mixed. As nicely reviewed by Bargh and Chartrand (1999), automaticity can result (1) intentionally, when people have an intentional goal of acquiring a skill, and (2) unintentionally, when people repeatedly make the same choices in the same situation. The former type of acquisition seems to clearly increase consumer welfare. The latter, however, may sometimes be beneficial (e.g., automatic detection of a frequently purchased brand speeds up shopping) and sometimes harmful (e.g., automatic detection of a frequently purchased brand prevents consideration of new or lower priced brands).

Several other types of beneficial effects have recently been identified by Beilock and Carr and their co-researchers (Beilock & Carr, 2001; Beilock, Beilock, Benett, Bertenthal, McCoy, & Carr, 2004a; Beilock, Culp, Holt, & Carr, 2004b; Beilock, Wierenga, & Carr, 2002) who have shown that automaticity reduces or eliminates the problem of “choking” under pressure (e.g., due to incentives, peer pressure, social evaluation, and time pressure) in both higher order mental tasks (e.g., modular arithmetic) and motor skills (e.g., putting in golf). However, they find that for motor skills, if pressure increases self-monitoring, experts are hurt more than novices--presumably because it disrupts otherwise automatic processes. These deficits can be overcome by training. Analogs in consumer behavior are not hard to imagine. Many purchase situations require higher order reasoning and mathematical skills (e.g., financing a house) and consumers can be pressured by sales representatives, friends and family, or time pressures created by market conditions. Similarly, many product usage situations require automatized motor skills (e.g., driving a car) and are subject to similar pressures.

Additional negative effects of automaticity are suggested by the research of Bargh and his co-researchers (Bargh & Chartrand, 1999; Chartrand & Bargh, 1996; Kay et al., 2004) who have shown that specific goals can be automatically activated without the awareness of the decision maker. For example, Kay et al. (2004) showed that mundane objects (e.g., a briefcase or boardroom table) increased competition and reduced cooperation as perceived in social situations and as acted upon in economic games. Balancing competitive and cooperative tendencies is a key aspect of many aspects of information search and decision making, especially when some degree of negotiation is involved. The extent to which automatically accessed goals are beneficial or harmful will depend on the extent to which they are appropriate to the situation and consistent with the explicitly held goals of the decision maker.

THEORY

Expertise cannot occur without learning. Thus, there is a sense in which theories of learning and theories of expertise are necessarily unified through the assumption that expertise arises as the result of maximal amounts of learning. Despite the obvious truth of this necessary unification, the literatures on learning and expertise are surprisingly separate. To be sure, there are areas of overlap and common foundations, but in actuality most theories of learning have been designed to account

for the early stages of knowledge development, typically explaining results of experiments in which subjects initially have none of the to-be-learned knowledge and acquire knowledge over relatively short periods of time (e.g., an hour to several days or weeks). In contrast, theories of expertise focus on the later phases of learning, identifying individuals who, over relatively long periods of time (usually years), have achieved levels of performance that surpass not just beginners, but others who have similarly large amounts of experience but have acquired less knowledge from that experience. Given this separation in the literature, we will review each area separately.

Models of Learning

The most straightforward way to organize models of learning is by the complexity of what is learned. As with overall theories of learning and expertise, distinct literatures have developed to account for the learning of simple and complex relationships among stimuli, response, and incentives in laboratory and real-world environments. At one end of this spectrum is the Pavlovian conditioning of a single stimulus to elicit a single response. In marketing, the conditioning of affective responses to brand names through exposures to advertising has been an important area of application. At the other end of the spectrum is the acquisition of an understanding of naturally occurring domains, including the logical and causal relationships among the elements of those domains. In marketing, information search and the development of differentiated brand concepts within (and across) product categories has been an important area of application. Although each end of this spectrum uses a rather different set of constructs, a shared foundation can be found in the principle most commonly called “the association of ideas.” Aristotle noted that mental states came to be associated with each other if they were similar to each other, contrasted with each other, or occurred together in time or space. The variations of this principle have been many, and the differences between applications have not been small (e.g., behaviorists of the mid-20th century denied any theoretical status to mental states of any kind and worked strictly with associations between stimuli and responses). Nonetheless, there is a clear and common core that is nicely summarized by Young (1968), “The principle has aspects: (1) that complex mental phenomena are formed from simple elements derived ultimately from sensations and (2) that the mechanism by which these are formed depends on similarity and/or repeated juxtaposition of the simple elements in space and time. The association of ideas provides a mechanism for ordered change through experience which complements (and plays an analogous role to) the concept of attraction (or gravity) in the physico-chemical sciences.”

Beginning with Chomsky’s (1959) critique of Skinner’s (1957) account of how language can be learned through conditioning, models of most human cognitive abilities have included more mechanisms than association (e.g., hypothesis testing, rule learning, production systems, etc.).³ However, few models of learning deny any role for conditioning and association, and many propose some variation of a dual system model in which low-level associative learning (and decision making) combines in some way with higher level mechanisms. These two systems underlie not just learning, but reasoning and decision making as well. Thus, they constitute integrated models of cognition (for reviews of dual system models of cognition see Sloman, 1996). It is beyond the scope of this paper to review all of these models, so we focus on two types of learning models that have been widely used in consumer research and illustrate the trend toward integrated dual system models—conditioning and concept formation.

Conditioning and associative learning. Traditional descriptions of conditioning state that a previously neutral stimulus (called the conditioned stimulus, CS) can come to elicit the same response as another stimulus that has a pre-existing association with the response (and is called the

unconditioned stimulus, US), if the CS repeatedly occurs immediately before or during the occurrence of the US. Rescorla (1998) has argued persuasively that this characterization oversimplifies current models and empirical results (especially for the animal learning literature). Nevertheless, this simple description has a natural and direct connection to advertising that has been investigated for some time and proved very useful (Allen & Janiszewski, 1989; Janiszewski & Warlop, 1993; Shimp, Stuart, & Engle, 1991; Stuart, Shimp, & Engle, 1987; van Osselaer & Janiszewski, 2001). Many types of advertising present a brand name (which initially has little or no affective response associated with it) together with content (pictures, music, words, etc.) that elicit positive affect based on pre-existing associations. The central thesis that has been studied is the extent to which that positive affect is learned as a conditioned response to the brand name. It is well-established that conditioning procedures using advertising in a laboratory setting result in increased brand attitudes. However, the explanation for these results has been controversial. The first explanation is direct transfer of affect. This is viewed as a Pavlovian conditioning mechanism that relies on simple associations and is a mechanism similar to those at work in the animal learning paradigms that dominate current research on conditioning (for reviews, including discussions of neural mechanisms, see Fanselow & Poulos, 2005; Staddon & Cerutti, 2003; Thompson, 2005). This type of learning should occur regardless of whether or not people are aware of the relationship between the conditioned and unconditioned stimuli (e.g., that Brand X always occurred with a picture of a cute kitten). The second explanation is inferential belief formation. This explanation asserts that people notice the relationship between the conditioned and unconditioned stimuli and make an inference about some attitude-relevant belief. For example, if kittens are used in advertising for facial tissue, consumers infer that the advertising is making a claim about superior softness, and their attitudes change to the extent that they value softness and believe the claim. Finally, several researchers have argued that the results for advertising may be due to demand artifacts (Darley & Lim, 1993; Kellaris & Cox, 1989). This too requires that people become aware of the relationship between conditioned and unconditioned stimuli, but reported attitudes change only because they deduce the goal of the experiment and desire to be cooperative. Kim, Allen, and Kardes (1996) report the results of several experiments that carefully rule out demand artifacts and show that both direct affect transfer and inferential belief contributed to attitude change; however, the awareness-dependent inferential mechanism was found to be the stronger component.

Concept formation. Concepts are the mental structures we use to represent our world. They can be discrete or continuous. Categories are discrete concepts (even if category membership is a matter of degree, as discussed earlier). For example, a mini-van is a type of automobile that can be distinguished from an SUV and a station wagon (even if some particular vehicles, like the Pontiac Aztec, are hard to classify). Among other things, consumers use discrete concepts to screen alternatives during the search phase of decision making. In contrast, choices among alternatives frequently involve continuous concepts like quality or market value. Both types of concepts must be learned over time so that new alternatives can be appropriately classified and evaluated. These components of consumer decision making closely parallel the major experimental paradigms in concept formation which present subjects with a multiattribute stimulus and require a discrete or a continuous response that reflects the subject is understanding some target concept.

The major theoretical models used to explain concept formation are of two primary types, typically labeled exemplar-based and rule-based models. Although there are many variations, exceptions, and nuances, exemplar-based models tend to postulate simple associative processes that can operate automatically and without significant cognitive resources. When some new thing is encountered, it recruits information from other concepts in memory that are similar to it and that information determines the response. If I see a new model of car that resembles a Dodge Caravan

and a Honda Odyssey, I am likely to classify it as a minivan and believe it to have a price and quality level similar to those vehicles. As mentioned, this might occur very rapidly with little conscious thought; however, it might also occur through a very deliberate process of reasoning by analogy, and models of both types have been proposed. In contrast, rule-based models assume that each stimulus attribute contributes more or less independently through some rule of combination (frequently linear) to form an impression of how well the instance fits the concept. If it is a tall, boxy, cab-forward car with room for seven people, it is probably a minivan. Prototype models combine aspects of both exemplar-based and rule-based models. They are like exemplar-based models insofar as the prototype is essentially the “average” or most representative exemplar of the category. However, in these models it is the only exemplar that is recruited for comparison to the to-be-classified stimulus. In this sense, it is very much like an abstract rule.

In both psychology and in marketing, there has historically been a split between research on the learning of continuous and discrete functions of multiattribute stimuli. For example, in psychology there has been extensive research into modeling the learning process in categorization tasks. This research paradigm has concentrated on binary classification tasks (frequently based on binary attributes), and has primarily focused on testing specific models (e.g., rule-based vs. exemplar-based models, see Kruschke, 1992; Medin & Schaffer, 1978; Nosofsky, 1984). In marketing, there have been studies using the categorization paradigm that have investigated consumer learning of brand or category membership based on categorical cues (e.g., Huffman & Houston, 1993; Hutchinson & Alba, 1991; van Osselaer & Alba, 2000). In general, categorization research in marketing has placed greater emphasis on category definition, the categorization processes, and category structure than on the learning of categories (e.g., Alba & Hutchinson, 1987; Cohen & Basu, 1987; Moreau, Markman, & Lehmann, 2001; Park, Iyer, & Smith, 1989; Sujan, 1985; although Sujan & Bettman, 1989 examined adding new brands to an existing product category).

The learning of functional relationships between (usually abstract) continuous cues and a continuous criterion has been extensively pursued in psychology using the multiple-cue probability learning (MCPL) paradigm (Hammond, 1955). MCPL research has shown that a wide variety of functional relationships between cues and outcomes can be learned, given sufficient trials and appropriate feedback, but that some relationships are more difficult to learn than others (see Brehmer & Brehmer, 1988 for a review; see also Camerer, 1981; Mellers, 1980). In marketing, the MCPL paradigm has been used by a number of researchers. Meyer (1987) demonstrated that consumers could quickly learn positive attribute-quality relationships in a multiattribute setting. West (1996) used an agent learning task to demonstrate that veridical feedback eliminates the facilitative effects of initial preference similarity and that learners allocate more time to informative than uninformative feedback. Hutchinson and Alba (1997) demonstrated a framing effect in a budget allocation task where past allocations and their sales results served as the stimuli and feedback. Hoch and Schkade (1996) used a managerial credit-forecasting and learning task to investigate the design of decision support systems.

A number of researchers have recently noted that, although there are large literatures on categorization and multiple-cue judgment, they seldom reference each other, and the two experimental paradigms are seldom combined in the same study (DeLosh, Busemeyer, & McDaniel, 1997; Eisenstein, 2002; Eisenstein & Hutchinson, 2006; Juslin, Olsson, & Olsson, 2003). Also, there is a considerable amount of recent research directed at comparing the ability of exemplar-based and rule-based models to simultaneously account for results in classification and judgment tasks (Juslin et al., 2003; Eisenstein & Hutchinson, 2005; cf. Tversky, Sattath, & Slovic, 1988). In general, both types of model do surprisingly well accounting for the main results of the past 30 years of research on concept formation. Exemplar-based models are challenged by results showing strong prototype

enhancement effects for discrete concepts and the robust ability of people to extrapolate beyond the set of exemplars they have encountered in making continuous judgments. Nonetheless, recent extensions of exemplar-based models perform admirably (Palmeri & Nosofsky, 2001). Rule-based models are challenged by observed patterns of errors that are hard to explain by any simple rule and by the ability of people to learn apparently complex relationships even though they cannot verbalize a rule that would predict their own behavior. To the extent that there is consensus across researchers, it is that (1) both classes of models do extremely well in accounting for most robust findings, (2) in certain “extreme” situations people seem to clearly use one or the other type of process, (3) hybrid models are therefore an “easy” solution, (4) there may be two separate systems that operate sometimes alone, sometimes sequentially, and sometimes in parallel, but (5) it is still possible that future research will yield a single unified model that relies on a single system (i.e., either rule-based or exemplar-based). Excellent reviews of the competing theories can be found in Ashby and Maddox (1998), Johansen and Palmeri (2002), Nosofsky, Palmeri, and McKinley (1994), and Palmeri, Wong, and Gauthier (2004).

Models of Expertise

Models of expertise have traditionally focused on explaining various aspects of skilled human performance. One question that arises is how experts are able to bring relevant information, inferential techniques, and other specialized skills to bear as quickly as they are observed to do. Given the slow computational speed of the human brain, it is somewhat surprising that experts are able to achieve high levels of performance as quickly as they do. In addition to the specific problem of skilled performance, we also discuss in this section an overarching theory of expert competence, with the goal of determining what characteristics of people and tasks are most likely to lead to the development of expertise. Finally, we examine attempts to model consumer expertise in a traditional economic framework.

Computation rate vs. knowledge base size. Experts are called upon to process complex decision inputs and to make accurate decisions quickly. There are two general ways to approach this problem: retrieval from memory and computational search. Retrieval from memory is a fast and relatively effortless process for humans; conditional on a match between the current situation and a past situation that has been stored in long term memory, retrieval is rapid and automatic (Ericsson & Kintsch, 1995). If it is discovered that there is no good match in memory, however, a slower computational search through the space of possible answers ensues to discover an appropriate course of action. Search is effortful and slower, but it is the foundation of general problem solving ability (Newell & Simon, 1972). The distinction between retrieval and search is analogous to the difference between knowing the answer and knowing how to compute the answer (e.g., most adults retrieve $5 \times 6 = 30$ from memory effortlessly, but need to laboriously compute $51 \times 29 = 1,479$). It is also analogous to the extensively discussed differences between declarative and procedural knowledge (e.g., Anderson, 1982; Cohen & Squire, 1980). There is an obvious tradeoff between knowledge and search. Building an extensive database of cases and committing them to memory is time intensive, though the costs can potentially be spread out over time. Learning procedural knowledge is frequently easier, but the actual computation is more effortful. The retrieval-search continuum represents the difference between the *cost of learning*, which is borne in the past, and the *cost of thinking*, which is incurred at the time of decision (cf., Eisenstein, 2002; Shugan, 1980).

Given the tradeoff between search and retrieval, it is reasonable to investigate the nature of isoperformance curves with respect to these two information processing mechanisms. The human brain is a slow information processor: it takes 5 to 10 seconds to store a chunk in long term memory

(Simon, 1974); the simplest operation of comparing two symbols in a memory search task takes about 40 ms (e.g., Sternberg, 1966); recognizing a letter takes approximately 10–20 ms (Sperling, 1963); and recognizing a familiar pattern or word takes about 200–400 ms (see Luce, 1986; Teichner & Krebs, 1974, for reviews). In addition, humans can only store and manipulate small numbers of items in short term working memory (Miller, 1956). These limitations imply two realities about expertise: first, expert performance is almost always based on retrieval rather than search; second, expertise is strongly tied to a given domain, because stored exemplars, case knowledge, and knowledge architectures are bound to domains. The clearest investigation of isoperformance between search and retrieval comes from studies of chess masters. In chess, human experts compete on nearly equal terms with computers that can search through nearly 200 million nodes per second (compared to humans, who can process approximately 1 node per second). Charness (1981) estimated the size of the knowledge base required to match computers' search capability at 50,000 to 100,000 stored positions. Although the order of magnitude of the number of stored exemplars may differ by domain, it is quite likely that similar effects would be revealed in many other areas of human expertise, from appraising collectables or houses to estimating the price of cars.

Given that expert performance is largely based on retrieval, a number of psychological questions arise. In particular, an expert's knowledge base must be accessible to be useful, but the larger the database, the slower we would expect the search for a given piece of information to be. However, experts are observed to make decisions faster than novices, leading to the question of how experts are able to marshal their knowledge quickly enough to be useful, given their large databases of knowledge. Several different knowledge structures have been proposed which demonstrate that, with appropriate architectures, search can be sufficiently fast. These architectures include symbolic processing models (e.g., Elementary Perceiver and Memorizer [EPAM], Feigenbaum & Simon, 1984), parallel distributed processing networks (e.g., McClelland & Rumelhart, 1988; McClelland & Rumelhart, 1981), and hybrid systems (e.g., Anderson's Adaptive Control of Thought [ACT] system, 1983; Hummel & Holyoak, 1997, LISA (Learning and Inference with Schemas and Analogies) analogical reasoning system; Newell, 1990, SOAR architecture). These models demonstrate that, although experts might be expected to have slightly slower access times than novices, such accessibility differences can be small if appropriate knowledge architectures are used to organize information, and therefore retrieval can remain the primary method relied upon by experts.

Shanteau's Theory of Expert Competence. Shanteau (1988a, 1988b) proposed the members of a given domain should set the standard for competent performance as well as indicating who are experts in the field. This proposal is a pragmatic means to avoid the thorny issue of an outsider determining objectively "good" performance in each domain. Conditional on the definitions of the relevant pool of people and the evaluative mechanism, Shanteau's theory proposes that expert competence is based on five factors: domain knowledge, psychological traits, cognitive skills, decision strategies, and task characteristics. From the point of view of marketing, these characteristics can be mapped onto typical situations faced by consumers to determine the likelihood of achieving expert level consumer performance.

Adequate *domain knowledge* is a prerequisite for expert performance. However, it is obvious that mere memorization of a laundry list of facts is not sufficient to guarantee expert-level decision making performance. This is because part of the domain knowledge that is needed comes from experience, which encompasses stored examples, anecdotes, and cases in long term memory, as well as the enrichment of the similarity metric that enables efficient matching of novel cases to stored examples. Shanteau (1988b) hypothesized that stored examples serve both as a mnemonic, so that experts remember rare possibilities, as well as a mechanism for experts to store large amounts of domain specific information.

Experts require specific *cognitive skills* in order to achieve high levels of performance. What these cognitive skills are depends on the specific task. For example, the task may require retrieving items from a large number of previously stored cases, the ability to perform well under pressure, or the ability to quickly recognize patterns, among other skills. Clearly, aspiring experts will have an advantage on tasks which load on these skills to the extent that their cognitive skills match the task requirements. In addition to cognitive skills, expertise requires mastery of specific *decision strategies*, which help experts overcome cognitive limitations. Most of these strategies are strongly domain dependent, but several are more generally applicable. Specifically, experts across many fields rely on decision aids to manage information, decompose complex problems into smaller sub-issues, prethink solutions to tough situations (when they are anticipatable), and make extensive use of feedback when it is provided (Shanteau, 1988a; Shanteau, 1992; Shanteau, 1988b).

Experts also possess certain *psychological traits*, such as “self-presentation — the creation and maintenance of a public image,” (Shanteau, 1992; Shanteau, 1988b). Surprisingly, such traits may be highly relevant for consumer expertise. For example, most people have a friend or acquaintance who knows “everything” about cars, computers, stereos, food, stocks, or other common consumer goods, and one characteristic of such “consumer mavens” is that they are able to maintain the self-presentation of expertise. Consumer research has not extensively investigated the role of these consumer experts, except in thinking about them as early adopters in Bass and other diffusion frameworks.

Finally, the role of *task characteristics* are often overlooked in the study of expertise. Many have argued that characteristics of the task are critical in determining whether there will be any bona fide experts in the domain (e.g., Alba & Hutchinson, 1987; Blattberg & Hoch, 1990; Hoch & Schkade, 1996; Hutchinson & Alba, 1991; Klayman, 1988; Shanteau, 1988a). A common observation is that in some domains experts achieve at very high levels, but in other domains, performance is not significantly different from novices (Brehmer & Brehmer, 1988; Carroll, 1987; Chi et al., 1988; Ericsson, 1996; Grove & Meehl, 1996; Meehl, 1954; Oskamp, 1962). In general, task characteristics that predict good performance include repetitive tasks that are based on static, agreed-upon stimuli with timely, veridical, feedback available, and a stationary underlying model, in which the unmodelable error in the environment is low. Task characteristics that suggest poor performance with little evidence of objective expertise include dynamic stimuli, domains stimuli with little agreement about which are important, nonstationary underlying processes, cases where feedback is either unavailable, nonveridical, delayed, or ambiguous. The list above is nonexhaustive, but it should give a flavor of what types of tasks are likely to result in high levels of observed human performance—tasks such as weather forecasting, solving physics, math, or programming problems, some areas of medical diagnosis, and related fields are likely to result in high levels of performance. Other tasks, such as predicting recidivism rates among potential parolees, admissions officers, etc. are likely to result in lower levels of performance.

Applying the Theory of Expert Competence to consumer domains, we see that we should expect the development of expertise across a wide variety of consumer tasks. For example, many consumers buy “collectables.” Some collectable purchases are priced using a typical retail take-it-or-leave-it formats. However, many collectables are sold at auction (e.g., on eBay) and others are sold at yard sales, flea markets, and other similar venues, which are not fixed price settings. Under such circumstances, we would expect that consumer expertise would develop, with some consumers able to accurately value objects within their domain of expertise. Similarly, experienced shoppers are likely to develop a reasonable sense of where to go for the cheapest product, if it is commonly purchased (though store choice is not usually determined by a single good). In other circumstances,

it is unlikely that consumers will develop substantial expertise. For example, people infrequently negotiate over automobiles, little feedback is available to the consumer after the deal, and the relevant attributes change over time. Therefore, we would expect very little expertise to develop among ordinary consumers in this market.

Human capital. Human capital is defined as scarce knowledge, skills, or techniques that are acquired through investments in formal education, training, or experiential learning. Much of the important work in this area has been done by Gary Becker (for a comprehensive review, see Becker, 1993). The majority of the work in human capital has focused on those investments that would provide returns in the labor market. However, in marketing, Ratchford (2001) extended the original Stigler and Becker (1977) human capital model by adopting the original household production model and by further viewing the household as a producer of goods and services that it sells to itself.

The Ratchford theory of consumer human capital begins with the assumption that each household or consumer can be viewed as a small business that produces a positive, real-valued vector of activities, Z . Each activity, Z_i , is produced by using a combination of goods, X , time, T_i , and knowledge K , which represents the types of knowledge capital needed to produce Z_i . Experience is assumed to lead to at least some relevant knowledge consistent with H1, learning from experience. With appropriate constraints and assumptions on functional forms, consumers are assumed to maximize utility subject to constraints on time, income, and production functions for each activity. The fundamental insight is that knowledge changes the relative cost of producing goods, because for example, an expert chef will find the cost to produce a meal relatively cheaper than a novice. Furthermore, it is assumed (in keeping with the perfect world framework) that consumption events provide experience that automatically increases knowledge capital. It should be noted that increases in human capital will result in an increase in consumption of a given activity, but may result in either an increase or a decrease for the input goods and time required. The increase in the consumption of the activity follows from the fact that human capital decreases the true, or total, cost to produce it. Although consumption for the activity will increase, consumption of the component goods and time required to produce the activity may decrease because human capital may cut the amount of goods and time required per unit of the activity, essentially increasing efficiency (Ratchford, 2001). This is analogous to the standard economic analysis of income and substitution effects, and the net result will depend on the particulars of a given situation.

If the human capital model is true for consumer behavior, there are a number of consequences, which are detailed in Ratchford (2001). First, apparent heterogeneity of tastes may be due to differences in the full price of a good across households, which is due, in part, to heterogeneity in human capital. Second, if knowledge capital accumulates with mere experience, in accordance with H1, then decisions to invest in search should occur more frequently in the early stages of the product cycle, where returns are greatest. Furthermore, the full price of the activity should fall through the lifecycle if input prices and time are held constant, though most rapidly in the early stages of learning when returns are greatest. Third, brand-specific knowledge is likely to create brand loyalty because the brand specific knowledge reduces the costs associated with using it. In addition, if information about attributes and prices that were learned in the past can still be used in the current search, then the total amount of search will be reduced. Moreover, if there is learning about how to search, then search costs are effectively lower, and increased total search will result. Finally, if consumers are rational, then they will search more in categories in which search leads to information or skill capital (e.g., Internet shopping on different sites).

METHOD

Measuring Expertise as Individual Differences

It is obvious that novices are different from experts in a variety of ways. In particular, novices are likely to be less accurate than experts in predicting outcomes of interest, by definition in some cases. However, it is reasonable for us to ask whether there are certain judgment strategies that frequently underlie expert performance. As discussed previously, a large knowledge base that allows experts to draw on a larger store of memorized facts is one difference that explains a portion the expert-novice performance difference. A large knowledge base allows experts to employ a case-based judgment strategy. Case-based strategies rely on the impressive human ability to judge similarity between cases. Using such a strategy, an expert compares the attributes of the current case to those stored in long term memory, and makes a judgment in the current case that matches the judgment made in the stored case. This is a common strategy in fields such as law or medicine (Carroll, 1987), but it is also employed by chess masters (Charness, 1981), and is likely employed by experts in other domains as well (e.g., case studies are often used in MBA programs, and it is likely that business people use them as well). Case-based strategies are likely to be most useful and accurate in highly predictable environments because, in such environments, any individual case will be quite similar to other similar cases (Hoch & Schkade, 1996).⁴ Using a case-based strategy, individual differences in the number of cases stored in long term memory and in the veridicality of the similarity metric will underlie differences in observed expertise. Importantly, there are two ways to learn the necessary case knowledge and similarity metric: experience and instruction.

Instruction is one of the most common ways that people become expert in a domain. For example, someone can take a course on computer programming and learn how to debug a program, or a doctor can attend medical school and become better than a novice at diagnosis. Instruction tends to be the primary path to skilled performance in most scientific and technical fields (Chi et al., 1988; Ericsson, 1996; Ericsson & Charness, 1994), which makes sense because these are fields in which “practice makes perfect” and in which there is an established base of facts and relationships to be mastered. Experience is another route to skilled performance, though the literature suggests that it is a much less successful path than instruction (Dawes, 1979; Eisenstein, 2002; Ericsson, 1996; Ericsson & Charness, 1994; Hoch, 2002; Klayman, 1988). Some people do appear to have learned complex rules that make them expert in a domain from experience. For example, Ceci and Liker (1986) showed that there exist experts at predicting the outcome of horse races (and their expertise extended to making money at it), and Einhorn (1974) showed that some pathologists used highly configural strategies in diagnosis. However, within both groups of experts, not all were accurate, and most were unable to articulate how they arrived at their predictions.

In fact, a robust finding is that many so-called experts (who may have substantial experience) are nonetheless inaccurate (Grove & Meehl, 1996; Meehl, 1954; Shanteau, 1988a). This appears to be most true when the environment of prediction has considerable unmodelable uncertainty in it, for example, when predicting the behavior of people (e.g., psychological or psychiatric diagnosis, financial forecasting). However, it is clear from numerous studies that mere experience is unlikely to lead to expert performance, contrary to H1 (learning from experience). As discussed earlier, the development of expertise is most likely when the task characteristics identified by Shanteau in his Theory of Expert Competence (Shanteau, 1988a; Shanteau, 1988b) are satisfied, and when the would-be expert has both the motivation and the ability to learn. Learning from experience is more difficult than learning by instruction, and the likelihood of developing expertise from experience is greatest when several conditions are satisfied. First, the outcome and the feedback relating to that outcome should be unambiguous. Second, the feedback about whether the expert’s prediction was

correct should be immediate (feedback that comes months or years later, as in many financial decisions, is not as helpful). Third, the number of experiences should be “large” (see Klayman, 1988, for a review). For example, learning how to appraise used cars is a skill that is likely to be learned from experience. But in order to learn the prices of used cars, the would-be expert must observe hundreds or even thousands of used car auctions, each time comparing his predicted price to the actual selling price, updating their knowledge base. Theory would predict that it would be much more difficult to learn medical diagnosis from experience, because outcomes are frequently ambiguous (or unknown), a critical input to the decision is probability, which is never directly observed, and when outcome feedback exists, it is temporally distant from decision making.

Amount of experience. Amount of experience is not a good predictor of performance (Ericsson & Charness, 1994; Grove & Meehl, 1996). This appears to be largely due to a subtlety in the definition of “experience.” For most people, experience is the amount of time spent “doing” an activity. For example, if someone had played tennis for 20 years, they would say that they had 20 years of experience playing tennis. It appears that it is not really mere experience that leads to improved performance. What is necessary is the explicit comparison of one’s performance with the correct outcomes. In the expertise literature, experience gained with the explicit goal of identifying discrepancies between one’s mental model and the true state of the world is called *practice* (Charness, 1981; Ericsson & Charness, 1994). Practice is highly correlated with expertise.

Objective vs. Subjective Knowledge. Two separate paradigms exist for identifying experts: an objective test can be administered, and those who score high enough are termed experts; alternatively, people can be asked for a subjective opinion of how expert they are in a given field (e.g., compare Brucks, 1985; Mitchell & Dacin, 1996). Both techniques have advantages and disadvantages. Objective tests of knowledge are best when there is an obvious true/false quality to the questions under consideration, where the investigator can verify the correctness of the answer given, and where the costs of testing are reasonable. Subjective expertise is cheap, easy to collect, and generally involves no more than self-reported scale measures. Obviously another approach, pursued by both Brucks and Mitchell and Dacin, is to collect measures of expertise and compare their efficacy in predicting outcomes of interest. Numerous researchers have found that self-reported expertise is not a reliable predictor of accuracy (Brucks, 1985; Ceci & Liker, 1986; Grove & Meehl, 1996; Meehl, 1954; Spence & Brucks, 1997), although other studies have found consistencies between self-reports and objective measures (e.g., Mitchell & Dacin 1996). Other than comparing the task characteristics under investigation to Shanteau’s Theory of Expert Competence (1988a), there does not appear to be a reliable method for predicting in which tasks self-reports will be a valid measure of expertise.

Experimental Paradigms

Given the breadth of what can be learned, and how people become expert, it should not be surprising that numerous different experimental methodologies have arisen. In this section, we provide an overview of the most important of them.

Test after Training. Perhaps the easiest paradigm for testing the acquisition of expertise is “test after training.” In this type of experiment, novices are brought into the laboratory and are exposed to initial “training” stimuli. During the training phase, a stimulus is presented, the subject makes a response, and immediate veridical feedback is given. Based on the feedback, the subject updates his knowledge base, and the training continues. Training may continue until a fixed number of repetitions has been reached or until the subject is able to achieve a predetermined level of accuracy (training to a criterion). Regardless of how training ends, at some point there is a test phase.

During the test phase, stimuli are presented and subjects make responses, but no feedback is given. Under the assumption that the decision weights (and learning) obtained by the end of training do not change without feedback, the test phase is then a test of the acquired knowledge (e.g., Brehmer, 1987; Eisenstein & Hutchinson, 2006; Mellers, 1980; Meyer, 1987; West, 1996).

Intentional vs. Incidental Learning Goals. Most people think of learning as a deliberate process, but learning may proceed both intentionally or incidentally. When learning intentionally, people tend to actively test hypotheses to uncover rules or generalizations that hold across several examples (e.g., Bruner et al., 1956; Eisenstein & Hutchinson, 2006; Hoch & Deighton, 1989; Klayman & Ha, 1987; Wattenmaker, 1993; West, 1996). Incidental learning refers to the learning of complex information as a side-effect of performing some other activity. When such learning proceeds without awareness of what has been learned, it is termed implicit learning. In a series of seminal papers, Reber (1967, 1969), characterized implicit learning by two principles: (1) knowledge is not fully accessible to the conscious mind, so that subjects cannot provide a complete (or in some cases, any) description of what they have learned; and (2) the process gives rise to abstract knowledge, meaning that what is learned is more complex than a simple association or frequency count (both of which are frequently studied in the implicit memory literature, see Berry & Dienes, 1991). From the point of view of consumer research, incidental learning is important because consumers typically are not in a strategic problem solving or learning frame of mind when they are being exposed to potentially useful information.

In the psychological literature, incidental learning has been investigated in memory tasks, the control of complex systems, sequence learning, correlation assessment, MCPL function-learning, and in the learning of artificial grammars (e.g., Berry & Broadbent, 1987; Nisbett & Wilson, 1977; Reber, 1967; Reber, 1969; Seger, 1994; Wattenmaker, 1993). Artificial grammars were pioneered by Reber (1967, 1969). In these experiments, subjects typically study and memorize strings of 15–25 letters produced by an artificial grammar. After learning, subjects are asked to evaluate whether novel strings conform to the grammar, and they usually achieve accuracy levels of 60–80% (Reber, 1989). This type of stimulus is not usually encountered in marketing, although the demonstration that subjects notice regularities in seemingly meaningless strings may have implications for advertising and branding research. Another paradigm has subjects learn covariation between features within visual stimuli or between a visual stimulus and a verbal label. Although the covariations are usually simple, subjects do not explicitly detect them, perhaps because they are a priori improbable or because they involve small alterations. (such as a covariation between women's hair length and their personality, e.g., Lewicki, 1986; Lewicki et al., 1997). These studies typically use latency time ("efficiency") as the dependent variable to demonstrate that learning has occurred. For these studies, the link to consumer research is more obvious, because the entire process of branding involves the unconscious association of a meaningless stimulus (the brand name or logo) and an affective response. The demonstration that people unconsciously pick up on such associations is interesting, and the fact that they learn the associations incidentally to performing other tasks implies that H1 of the perfect world hypotheses may be more likely. Unfortunately, the correlations that are generally studied are considerably simpler than standard consumer-usage stimuli, and the incidental tasks are more focused, less noisy, and atypical of consumer behavior. MCPL function-learning represents the prototypical experiment in the MCPL stream in which subjects must learn the relationship between cues and a criterion from outcome feedback. Some subjects may intentionally learn these relationships, but evidence exists for substantial incidental learning (e.g., Eisenstein, 2002; Eisenstein & Hutchinson, 2006). Consumers may pick up incidental functions when learning prices in a market, or when learning attribute-quality relationships. Dynamic systems learning is similar to MCPL function-learning, as it requires subjects to control the value of an outcome vari-

able by changing another variable. For example, in Berry and Broadbent's (1984) study, subjects had control over the size of the workforce in a sugar factory, which they used to control the amount of sugar output. Subjects who learned the dynamic system showed both explicit knowledge and implicit knowledge that was acquired incidentally, and their performance differed greatly from their explicit knowledge.

Overall, results from incidental learning experiments demonstrate that subjects can learn a substantial amount without being able to verbalize that knowledge, and that substantial amounts of expressible knowledge can be learned without deliberate attention to the learning process, supporting H1. Proponents of implicit learning argue that a counterintuitive characteristic of implicit learning has been robustly demonstrated: conscious attempts to discover and learn a pattern sometimes impede learning, at least when the pattern is not simple (see Howard & Howard, 2001). Lack of conscious awareness is typically demonstrated by subjects' inability to verbalize what they learned, or by a dissociation between confidence and accuracy such that subjects are (uncharacteristically) underconfident. However, there is considerable debate as to exactly what is being learned incidentally, how that knowledge is represented, and how transferable the knowledge is to new situations (e.g., see Dienes & Berry, 1997, and the antecedent articles). A reasonable integrative view would be that both intentional and incidental learning processes are likely to play a role in learning in many naturalistic environments.

In marketing, few studies have directly examined incidental or implicit learning. Typically, those studies that have been done have examined the learning a simple contingencies between two events or variables, such as attributes and price, or products and benefits. Most of the research has found that learning is successful, but only in some situations. For example, research on covariation assessment has found that consumers are able to learn contingencies between two variables such as price and quality (e.g., Bettman et al., 1986), but this learning is strongly biased by prior beliefs (Alloy & Tabachnik, 1984). Since simple contingencies are difficult to learn, more complex informational environments should present even greater problems. More complex stimuli introduce problems of selective attention and information overload (Eisenstein & Hutchinson, 2006; Hutton et al., 1986; Meyer, 1987), and the results in more complex domains depend critically on situational factors, including distracter stimuli, memory load, and learning goal (e.g., Hutchinson & Alba, 1991).

Feedback and Incentives. One of the necessary conditions for the development of expertise is receiving veridical feedback. We will follow the definition of Kluger and DeNisi (1996), and define feedback as "actions taken by an external agent to provide information regarding some aspect of one's performance on a task." Feedback is frequently combined with an incentive to get the answer correct. In the real world, such incentives take the form of arbitrage opportunities, promotions, or other payoffs for getting the answer right. In laboratory settings, incentives are typically structured by the investigator so that subjects are better off when they answer correctly. Contrary to popular wisdom, neither feedback nor incentives are sufficient to guarantee the development of expertise, and in some cases either may reduce the rate of learning.

Feedback can refer to outcomes or to the process used to arrive at those outcomes. For example, someone attempting to learn the link between attributes and product price at an auction could be given feedback about the actual transaction price for each product (outcome feedback) or they could be given information about how they weighted the input attributes to arrive at their answer (i.e., process feedback, possibly derived from a regression model of their judgments), or both. Both outcome and process feedback are frequently used in learning experiments (e.g., Brehmer, 1980; Eisenstein & Hutchinson, 2006; Hammond et al., 1973; Mellers, 1980; Meyer, 1987). Most people believe that feedback improves performance, and there is no shortage of studies to provide evidence

for this position (e.g., Brehmer, 1987; see Klayman, 1988, for a review; Mellers, 1980). However, taken as a whole, improvements from feedback have been mixed, and the effect of feedback interventions (FI) has ranged from positive to negative. In their meta-analysis, Kluger and DeNisi (1996) found that, although the average Cohen's d for feedback interventions was .41, nearly 38% of all feedback interventions decreased performance (resulting in a negative d). They proposed a feedback intervention theory (FIT) to predict the effect of a feedback intervention based on: (1) the cues of the feedback message, (2) the nature of the task, and (3) situational and personality variables. Specifically, FIT proposes that feedback may interfere with learning for a number of reasons. First, feedback may direct attention away from some details of the task toward higher-level constructs (such as attention to self-esteem, general executive functions, or evaluation of performance, e.g., Vallacher & Wegner, 1987). Second, feedback may evoke a standard or evaluation criterion which changes the attentional allocation in the task, in which case improvement will result if attention is directed toward meaningful stimuli, or if increased attention allows bad hypotheses to be rejected, but negative effects result if attention is directed to nonproductive stimuli or hypotheses (Eisenstein & Hutchinson, 2006; cf., Kluger & DeNisi, 1996).

Economists love incentives, and typically assume that incentives will increase effort, motivation, and persistence. However, incentives are not universally helpful, and additional effort does not always result in improved performance. Like the effects of feedback, the effects of incentives are complex and vary depending on characteristics of the task and the learning environment (Bonner et al., 2000; Camerer & Hogarth, 1999; Hertwig & Ortmann, 2001, for reviews; see Jenkins et al., 1998). In general, incentives improve performance most in tasks where increased effort is likely to result in better performance, such as memory/recall tasks, MCPL, clerical tasks, and motor tasks (the latter two because they are otherwise boring, and incentives maintain effort). Incentives are likely to have no effect when intrinsic interest in the task is high (because motivation is already at a high level). And incentives are likely to hurt performance in tasks that require flexibility in mental models (e.g., Gestalt "set" and problem-representation tasks such as brain teasers) and when it would be better to rely on automatic processes (e.g., "choking" in sports, test anxiety). Task characteristics are important because it has been found that additional motivation to perform well is helpful mainly in tasks where little cognitive effort is required (see Ackerman, 1987 for a review), and increased motivation to perform can disrupt automaticity, causing decreases in performance (i.e., "choking" or similar performance anxiety, cf., Vallacher & Wegner, 1987). In addition, a seminal paper by Hogarth and Gibbs (1991) demonstrated that if the incentives are too "exacting," meaning that subjects are strongly penalized for errors, then incentives lowered overall performance.

Quantitative Modeling

Regression and Bootstrapping. Let us assume that we have an expert, and that this expert is more accurate than a novice at making a decision. One reasonable idea would be to try to capture the judgment strategy, or "policy," of the expert, so that others can derive the benefits of expert decision making without requiring input from the expert herself (e.g., Brehmer, 1987; Eisenstein & Hutchinson, 2006; Meehl, 1954; Meyer, 1987; Spence & Brucks, 1997; West, 1996). Policy capturing is the process of deriving a model of the expert's judgment. When the model of an expert is used to make predictions, rather than the expert herself, this is called "bootstrapping" (in the sense of "pulling oneself up by the bootstraps," Meehl, 1954). Usually, policy capturing uses regression to create a linear model of the expert by modeling the outcome as a linear combination of the inputs, which are called "cues." The first priority in capturing a policy is to define the judgment that is to be modeled in such a way that it is understood by the expert to be modeled, and so that the outcome,

or “criterion,” is properly operationalized. Most commonly, the criterion is operationalized as a rating on a continuous scale (i.e., a scale measure or a continuous prediction such as probability), although discrete choice tasks are also used. After defining the outcome or criterion, a prototypic procedure would be to have an expert make judgments for a large number of naturally occurring (i.e., “real”) cases, and then to use the cues and judgments from these cases to form the dataset for the regression model. Of course, this procedure suffers from all of the standard limitations of an observational study, the most significant being the lack of control over cue leverage, outliers, and cue intercorrelations, all of which may distort the parameter estimates (Brehmer & Brehmer, 1988). These limitations suggest an alternative approach based on conjoint analysis, in which cues and distributions of levels of the cues are chosen, a series of profiles are created, and the expert judgments of these conjoint profiles are used to construct the regression model.

To begin with, the policy analyst must choose which cues to include. Frequently, the number of cues will have to be whittled down to a manageable number through interviews with experts in the domain of study (e.g., Hammond et al., 1977; Wind et al., 1989). The selection of cues is obviously a critical step, because omitted cues will introduce substantial bias into predictions and will further distort the task. Fortunately, experts tend to report using more cues than they actually do (Shanteau, 1992), so this procedure is more likely to include unimportant cues than to omit relevant ones. After choosing the cues, a context is defined, the cue distributions are developed, and cue intercorrelations are determined. The use of correlated cues is somewhat different than in a typical conjoint study, in which cues are frequently orthogonal, but the point is to try to match as closely as possible the actual environment to be modeled so as to avoid inadvertently slipping away from the expert’s domain of competence. After setting up these prerequisites, the expert is exposed to multiple stimuli that consist of the cue profiles that have been defined, and she renders a judgment for each stimulus on the criterion scale. The policy analyst then regresses the criterion onto the cues to determine cue weights.

Although the conjoint-based approach to policy capturing may seem natural to consumer researchers, it has significant limitations (Brehmer & Brehmer, 1988). First, it is critical to keep both the task context and the output response mode (i.e., rating, ranking, choice) as close to that which the expert normally uses as is possible. This is because deviations in response mode or in presentation of the cues can disrupt various psychological processes that underlie expertise, including the retrieval of stored exemplars from memory, perceptual fluency in processing the cues, and overlearned or automatic cue integration procedures that experts normally use (imagine, for example, sitting on an admissions committee and evaluating candidates using unfamiliar scales for test scores and GPAs). These disruptions can cause experts to construct judgment rules on the fly, rather than using the previously stored policies that should be captured (see Brehmer & Brehmer, 1988, for a review; see also, Eisenstein, 2002; Eisenstein & Hutchinson, 2006). For the same reasons, the task should be designed to be as representative as possible. Other questions arise regarding the linearity of the model used by experts, whether to include interactions or not, and whether correlations or beta weights should be used as the reported outcome.

A frequent finding is that “bootstrap” models of an expert outperform the expert himself (Dawes, 1979; Grove & Meehl, 1996; Meehl, 1954). This is largely due to the fact that the model has no inconsistency in its predictions (see Camerer, 1981 for a comprehensive treatment).

Time-Series Analyses. Another way to model the development of expertise is to examine gains in expertise that accrue from training. One possibility is simply to look at people with different amounts of training, practice, or education in a domain, although this design suffers from the standard problems of cross-sectional analysis. Another approach is to do a longitudinal study of subjects as they progress through a training program. For example, Lehman, Lempert, and Nisbett

(1988) investigated the effects of graduate training on reasoning ability using both cross-sectional and longitudinal comparisons, and they found evidence that graduate training did increase reasoning ability, albeit differentially by field of study.

Longitudinal studies take a long time, and they suffer from other confounds as well. Another possibility is that researchers can bring otherwise naïve subjects into a laboratory, train them to perform some task, and can analyze the pre- and post-training data (e.g., Eisenstein & Hutchinson, 2006; Hoch & Schkade, 1996; Meyer, 1987; West, 1996). Frequently, training proceeds not just through a single pre- and post-test, but rather through a series of repeated study–test cycles. For example, a subject might receive feedback regarding his or her performance for an X trial study block, which could be followed by a Y trial test block in which stimuli were presented, but no feedback given (e.g., Meyer, 1987). The study–test cycle would then repeat a number of times, and the resulting data can be analyzed to generate a “learning curve,” or a model of the rate of improvement.

Our intuitions and experience tell us that most tasks that we perform become faster with practice. What is surprising, however, is that the rate and shape of improvement appear to be common across many types of task. Specifically, learning curves demonstrate rapid improvement followed by diminishing marginal returns to further practice, which is a pattern that is usually modeled with a power function.⁵ The widespread use of power functions to model learning curves has given rise to the phrase “the power law of practice.” Power laws are ubiquitous, and have been demonstrated in physical tasks such as pressing buttons or rolling cigars (Newell & Rosenbloom, 1981), in mental tasks such as generating geometry proofs, writing books, mental arithmetic, and reading inverted text (Delaney et al., 1998; Newell & Rosenbloom, 1981; Ohlsson, 1992), and in myriad other tasks of both long and short duration (see, Heathcote et al., 2000, for a review). The ubiquity of learning curves has been noted for over 100 years, and it appears that multiple underlying processes explain their existence. For example, it has been proposed that learning curves arise from error correction (Ohlsson, 1992). Alternatively, learning curves could be explained by “horse race models,” in which response time is a function of the fastest retrieval time among memory traces (e.g., Logan, 1988). ACT-R (Anderson, 1993) and SOAR (Newell, 1990) explain learning curves in different ways. ACT-R postulates that stored rules and memory traces are strengthened according to a power law, and applications of SOAR have explained the power law as arising out of hierarchical learning that begins with low-level, widely applicable actions and proceeds to learn larger, infrequently occurring patterns. Overall, learning curves represent one of the great triumphs of cognitive psychology. They provide substantial evidence that learning is ubiquitous, they provide a mathematical framework (“law”) to use in modeling the rate of improvement, and the explanations above provide process explanations for why the mathematical structure should hold.

CONCLUSIONS

In this chapter, we have reviewed consumer learning and expertise from two complementary perspectives. First, we examined the evidence supporting and challenging a “perfect world” perspective in which (1) increases in familiarity lead to increases in expertise (i.e., learning from experience) and (2) as expertise increases, people become better and more efficient in their roles as consumers (i.e., improved consumer welfare). The evidence is mixed, but it generally supports the conclusion that this perspective holds as a first approximation or stylized fact. However, not all experience leads to expertise, and expertise sometimes has costs, many of which are due to overconfidence in and overgeneralization from one’s knowledge. Second, we presented a “toolbox” of theories and methods that have been found useful in research on learning and expertise. Our toolbox is cer-

tainly not exhaustive, but it does cover a wide range of work in both areas. Thus, we hope the reader is now better prepared to address the what, why, and how of research on consumer learning and expertise in their own work.

NOTES

1. A more extensive treatment of this topic can be found in Hutchinson, Eisenstein, and Alba (2007).
2. Knowledge calibration is a form of metacognition, which is defined as a person's knowledge and beliefs about any type of cognitive process or mental activity. For a discussion of marketplace metacognition and social intelligence, see Wright (2002).
3. An interesting historical review and commentary on this divergence can be found in Bargh and Ferguson (2000).
4. To see this, imagine a world with an $R^2 = 1.0$. Obviously, for any combination of X's, all that is necessary is to have a single observation with the same X values and the prediction will be exact. Furthermore, linear interpolation will also be zero-error.
5. See Heathcote, Brown, and Mewhort (2000), however, who claim that individual-level improvements are better modeled by an exponential, rather than a power function. The question of whether learning curves follow exponential or power functions is not devoid of theoretical content. If learning follows an exponential function, then learning is based on a fixed percentage of what remains to be learned, whereas if learning follows a power function, then the rate of learning slows down.

Categorization Theory and Research in Consumer Psychology

Category Representation and Category-Based Inference

INTRODUCTION

To make sense of the myriad new and existing products and services in the marketplace, consumers construct and use categorical representations to classify, interpret, and understand information they receive about these products and services. We define a *consumer category* as a set of products, services, brands, or other marketing entities, states, or events that appear, to the consumer, related in some way. We define a *categorical representation* as information that becomes stored in the cognitive system for a consumer category, and that is later used to process it.¹ One important use of category representations is during *categorization*, when consumers use these representations to assign a particular product or service to a consumer category, so that they can understand and draw inferences about it. Consumers might classify a new product as an MP3 player on the basis of prior knowledge about physical or functional features of MP3 players, for example, that MP3 players store music efficiently, are small in size, and are rectangular in shape. Once the new product is categorized, prior categorical information about MP3 players may also be used to make inferences about unknown attributes or features of the new product, or to form an evaluation of the new product.

From a marketing perspective, a number of questions about categorization have been examined that have implications for marketing decision making. For example, how should a new product be

positioned so that consumers can identify it as belonging to a particular product category? How can it be differentiated from competitors in the same category? How should the structural aspects of a product or consumer-relevant category be measured? What factors increase category flexibility and acceptance of new category members? If a new product is introduced with an existing brand name (e.g., Kraft microwave popcorn), how will the existing brand image (e.g., Kraft) affect its categorization? How will the image affect its acceptance? What contextual, environmental and individual difference variables influence acceptance of a new category member (e.g., a brand extension)? Will a brand (e.g., Kraft) be perceived differently if it includes a very different category (microwave popcorn) than prior existing members of the category (macaroni and cheese, cheese slices, etc.)?

Research in consumer psychology has studied categorization concepts by examining product categories (e.g., Herr, 1989; Loken & Ward, 1990; Meyers-Levy & Tybout, 1989; Sujan, 1985; Viswanathan & Childers, 1999), brand categories (e.g., Barone & Miniard, 2002; Boush & Loken, 1991; Boush et al., 1987; Cowley & Mitchell, 2003; Lee & Sternthal, 1999; Park, Milberg, & Lawson, 1991; Wanke, Bless, & Schwarz, 1998), goal-related categories (Ratneshwar, Barsalou, Pechmann, & Moore, 2001; Ratneshwar, Pechmann, & Shocker, 1996; Ratneshwar & Shocker, 1991), attribute-based categories (Hutchinson, Raman, & Mantrala, 1994), cultural categories (Aaker & Lee, 2001; Briley & Wyer, 2002), product user categories (Pechmann & Knight, 2002), and the self as a category (Sujan, Bettman, & Baumgartner, 1993; Aaker, 1999). In 1987, two decades ago, the categorization literature was reviewed in two seminal consumer psychology publications (Alba & Hutchinson, 1987; Cohen & Basu, 1987). At that time, the field of categorization research was relatively new to consumer psychology researchers. Both reviews included discussions of the major theories of categorization and empirical findings from publications in cognitive, social, and consumer psychology. Since that time, an upsurge of consumer research has occurred in the area of branding, an area that draws heavily from categorization theories. Consumer research has also shifted from an emphasis on brand and product benefits to an emphasis on consumer goals and contextual factors that impact the types of representations retrieved from memory (Loken, 2006). Research on consumer goals and contextual influences, like research on branding, draws heavily from categorization research.

In the present chapter, we build on the 1987 reviews by addressing theoretical and empirical research in consumer psychology in the subsequent two decades. The organization of this chapter uses a framework that reflects the structure of the basic science underlying the reviewed research, in particular addressing two general areas of study, *category representation* and *category-based inferences*. Within each of these sections, we discuss the types of consumer research questions that have been addressed. In the first general section, on category representation, we describe theory and research that addresses the nature, structure, and functional location of category representations. We provide a brief overview of the three prominent historical views of category representation, including the prototype, exemplar, and connectionist views (for more extensive discussion of these views, in cognitive psychology, see Barsalou, 2003a,b; Murphy, 2002; Smith & Medin, 1981; for further discussion of prototype and exemplar views in consumer psychology, see Cohen & Basu, 1987, Alba & Hutchinson, 1987).

Next we discuss the dual roles of category representations as both stable and flexible. Flexibility of category representations has been shown in recent literature of consumer psychology in the context of consumer goals and research on malleable self (and cultural) views. We also discuss consumer research that addresses the question of the conditions under which a specific category representation will be activated in a given context. Finally, we close the topic of category representations by addressing an emerging research direction within cognitive psychology on the functional location of category representations in consumers' memory. We introduce Barsalou's

(1999) proposition that representations reside in the brain's modality-specific systems. This work is important because the assumptions underlying the nature and neural location of category representations in Barsalou's theory departs significantly from the assumptions underlying previously-developed theories. We review consumer research that is consistent with this theory and call for future research that demonstrates and tests the theory in a variety of consumer contexts and across different sensory modalities.

In the second general section of this chapter we examine the role of category-based inferences in consumer judgments, particularly with respect to brand categories. Brand categorization research emerges as a prominent research direction of the prior two decades, with researchers studying the conditions under which category-based inferences are generated and used in judgments, particularly when a brand extension (a new category member) is introduced to the consumer. We examine the role of similarity (e.g., between a category and a new category member) in forming category inferences, together with when and how new instances of a category (e.g., new brand extensions) impact existing category representations and vice versa. Also in the context of brand categories, consumer researchers have examined factors that increase category expansion and acceptance of new category members, or flexibility in category structure. We demonstrate that factors that increase category expansion and flexibility often work through their impact on consumer perceptions of similarity. Building on research that addresses category structure and similarity, we analyze the important relationship between prototypicality and affect, and alternative theoretical explanations for the conditions under which a positive relationship will be demonstrated.

Finally, we conclude this chapter by summarizing the methodologies and analytic techniques that categorization researchers in this area typically use, and then offer some final conclusions about research on category representations and category-based inferences.

HISTORICALLY SIGNIFICANT VIEWS OF CATEGORY REPRESENTATION

Prototype, exemplar, and connectionist theories represent three prominent accounts of how categories are represented in memory. The prototype view assumes that categories are represented by abstract composites, called prototypes, based on central tendency information. These summary representations are based on the most likely features of the category's instances, based on a person's experiences with category members (e.g., Rosch & Mervis, 1975). The features in a prototype need only be probable of the concept, not necessary and sufficient. Categories are assumed to have graded structure, such that some category members are more representative, or typical, of a category than other category members. For example, popcorn is more representative than yogurt of the snack food category. The brand iPod is more representative of MP3 players than the brand Rio Sport. Within brand categories, the product Diet Coke is more representative of the Coca-Cola brand than Vanilla Diet Coke. In general, greater feature overlap with common features of the category is presumed to increase a category member's prototypicality. A new stimulus is classified as a category member to the extent that it is more similar to the category prototype and less similar to competing category prototypes.

The exemplar view assumes that categories are represented by specific, stored instances of the category, rather than by general, abstracted prototypes. An exemplar is often viewed as a representation of a specific category instance (e.g., a specific MP3 player, such as iPod). Some exemplar theorists, however, assume that an exemplar can also be a subset of a category (e.g., sedans as a subset of automobiles), its representation consisting of other exemplars or a conceptualization of the subset's features. According to exemplar theorists, a new stimulus (e.g., an ad for a new MP3 player) acts as a retrieval cue to access similar exemplar representations (e.g., iPod) in memory. The

stimulus is classified as a member in the category to which it has the most similar stored exemplar representation (Medin & Schaffer, 1978).

Finally, the connectionist approach (McClelland & Rumelhart, 1985) views categories as attractors in dynamic feature spaces. This view assumes that people establish correlations of features that co-occur for a category (e.g., MP3 players) by tuning associations between features in a network to represent these feature configurations. A new stimulus then activates the most similar feature configuration in the network (i.e., an attractor), which then captures the stimulus, and assigns it to the associated category.

STABILITY AND FLEXIBILITY IN CONSUMER CATEGORY REPRESENTATIONS

Regardless of the approach taken to representing categories, category representations must be both stable and flexible if they are to explain the information processing activity that underlies consumer behavior. The consumer environment is complex and ever changing. Thousands of new products are introduced in the marketplace each year. To keep up with these changes, consumers need two types of information processing capabilities. On the one hand, they need stable representations of products and brands in memory that relate veridically to their environment. These stable representations provide a foundation upon which consumer information processing can take place. They are important for recognizing, interpreting, and evaluating both objects and events in a wide variety of consumer environments. Simultaneously, however, these object and event representations require considerable flexibility, as consumers adapt them to an unlimited number of situations and unexpected changes in the environment. We address stability and flexibility further in turn.

Stability of Category Representations

Structure and stability of product categories. A number of consumer studies have sought to understand the determinants of prototypicality and the underlying structure of product categories. Some of these studies have assessed degree of prototypicality through analysis of a category's features or attributes, using measures such as *family resemblance* (Rosch & Mervis, 1975; in the consumer literature, Loken & Ward, 1990; Viswanathan & Childers, 1999), *ideals* (Barsalou, 1985; in the consumer literature, Loken & Ward, 1990; Viswanathan & Childers, 1999), *attribute structure* (Loken & Ward, 1987, 1990), and *fuzzy set-based* measures of category membership (Viswanathan & Childers, 1999; for a more complete discussion of these measures, see Barsalou, 1985; Loken & Ward, 1990; and Viswanathan & Childers, 1999.) Implementing these attribute-based measures often requires obtaining preliminary data to determine the attributes or ideals that are salient or accessible for a particular product category. Attribute-based measures are then correlated with various measures of prototypicality (e.g., Barsalou, 1985; Loken & Ward, 1987, 1990; Viswanathan & Childers, 1999). Across many studies, these attribute-based measures have been found to predict prototypicality measures well (Barsalou, 1985; Loken & Ward, 1990). For example, Loken and Ward (1990) found that a global typicality measure was significantly ($p < .05$) correlated with both an attribute structure measure ($r = .68$ for 8 subordinate and $r = .33$ for 8 superordinate product categories) and an ideals measure ($r = .64$ and $.51$, $p < .05$, for the same 8 subordinate and 8 superordinate categories). Viswanathan and Childers (1999), almost a decade later, made small modifications to the Loken and Ward (1990) attribute and exemplar lists, and recomputed the correlations for 8 of the original 16 categories with an updated sample. For categories at both the superordinate and subordinate levels, significant correlations again occurred between global typicality measures and attribute structure ($r = .47$ for the 4 subordinates, and $r = .42$ for the 4 superordinates); significant

correlations also occurred between global typicality measures and ideals ($r = .69$ and $.64$, for the 4 subordinates and 4 superordinates, respectively). These correlations show that predictions with the ideals measure were very stable from 1990 to 1999. Prediction with the measure of attribute structure changed somewhat from the 1990 to the 1999 study, which may reflect expected changes over the course of a decade in category composition, or even in minor changes of attributes across the nine-year period. Viswanathan and Childers (1999) also found that two fuzzy-set measures that assessed representativeness at the attribute level also predicted typicality very well (reverse scored, with global typicality, $r = .72$ and $.55$ for the four superordinates and $.75$ and $.93$ for the four subordinates). As these results illustrate, the structure of product categories, both at the superordinate and subordinate levels, appears quite stable over time and across different product categories.

Structure and stability of emotion categories. One might expect emotion categories (e.g., anger) to be more unstable than other types of categories. However, research in consumer and social psychology suggests that even emotion responses exhibit stability. Over time, people provide reliable measures of emotion categories, as shown in Richins' (1997) review and development of scale descriptors for thirteen emotional states in consumption situations. Ruth (2001) further finds that when the description of an emotion in the tagline of an advertisement (e.g., affection) is congruent with a description of an emotion expressed in the ad (affection), people prefer the ad to one in which the emotions described are incongruent (affection and joy). Furthermore, emotionally-valenced product attributes that are bipolar opposites appear to be related in memory, such that priming one (e.g., healthy) can activate the other (unhealthy), as demonstrated through how product information is interpreted (e.g., "more sweeteners" is interpreted as unhealthy) and how it impacts brand evaluations (Park, Yoon, Kim, & Wyer, 2001). Together, these findings indicate that emotionally-valenced attributes of product and brand categories exhibit properties of stability.

Flexibility of Category Representations

Consumer goals and category flexibility. Research also supports the conclusion that category representations are flexible. Categories do not take the same form across different contexts or situations; the perceived structure of a category depends on goals that are salient at a particular time or in a particular context (Barsalou, 1982). Evidence in consumer psychology also supports this conclusion. For example, Ratneshwar and Shocker (1991) found that prototypical "snack foods" differed from prototypical "snacks that people might eat at a Friday evening party while drinking beer." The contextual information relevant in the latter judgment focused consumers selectively on goal-relevant attributes of the product (e.g., saltiness or convenience) that differed from attributes underlying snack food judgments more generally (e.g., saltiness, sweetness, portability, convenience). Data on brands and types of beverages (Hutchinson, Raman, & Mantrala, 1994) also support the need to consider consumer usage situations when asking consumers to recall relevant brands.

Barsalou (1983, 1985, 1987, 1989) argued that individuals actively construct cognitive representations toward achieving goals. Multiple goals associated with a category may coexist within a single individual (Sengupta & Johar, 2002). Ratneshwar, Pechmann, and Shocker (1996) found that when consumers could not meet the needs of two different goals that were salient with a single product, or when they experienced goal ambiguity, they were more likely to consider alternatives from different product categories. In other words, members of a goal-derived category crossed traditional product category boundaries (also, cf. Johnson's, 1989, research on noncomparable alternatives). In this study, consumers who experienced goal ambiguity chose consideration sets on the basis of brand names, whereas consumers who experienced goal conflict chose consideration sets

on the basis of mixed categories to meet different goals (and postponed conflict resolution to a final stage). Ratneshwar, Barsalou, Pechmann, and Moore (2001) argued that similarity perceptions are influenced, not only by surface-level resemblances, but also by salient personal and situational goals. Although surface resemblance was important—for example, a granola bar was perceived as more similar to a candy bar than to fruit yogurt—goals were also important. Individuals for whom a personal health goal was salient rated the granola bar as more similar to fruit yogurt than to a candy bar, as long as other situational goals (convenience) were not also salient. Individuals for whom the situational goal of convenience was salient, and for whom a personal health goal was not salient, rated an apple as more similar to a donut than to an orange.

Contextual factors and category flexibility. Evaluations of category members also have been found to depend on contextual factors. Wanke, Bless, and Schwarz (1997, as reported in Wanke, Bless, & Schwarz, 1998) found that when consumers' task instructions encouraged them to place two disparate concepts (wine and lobster) in the same (versus different) category, the evaluations of these category members varied. For example, *wine* was rated more favorably when it was categorized together with *lobster* than when it was categorized separately.

When a really new product is introduced to the market, information from multiple categories may be relevant. Moreau, Markman, and Lehmann (2001) demonstrated that changing the salience of these categories influenced the extent to which they were used in making inferences about the new item. Information about the category that was encountered first, or cued by an ad, influenced consumers' categorizations, expectations, and preferences for the new product to a greater extent than category information encountered subsequently.

Flexible cultural and other self-views. A fundamental way of organizing information received from the environment is with respect to the self (Markus, 1977). The self category can be viewed as flexible or malleable (Aaker, 1999; Markus & Kunda, 1986). In consumer psychology, different self-views can be retrieved from memory and used in judgment, depending on situational cues. For example, an individual may view oneself as having several different personality traits, and when situational cues make a particular trait salient, brands that match the trait will be better liked (Aaker, 1999). Thus, different views of the self (see, also, Reed, 2004) can cue different categories, which are then used in subsequent processing.

When consumers are bicultural, they more easily retrieve and use both cultural views, as compared with monocultural consumers (Lau-Gesk, 2003). Situational cues can make different cultural views salient (e.g., independent versus interdependent views, Briley, Morris, & Simonson, 2000; Aaker & Lee, 2001) leading to different outcome effects (e.g., Forehand & Deshpande, 2001; Briley & Wyer, 2002; Mandel, 2003). For example, different views of the self (independent versus interdependent) have been found to vary in terms of category representations that are accessible for each. Interdependents, who were asked to describe their thoughts in response to an advertisement, listed more specific category exemplars than did independents (Ng & Houston, 2006). Situational cues can also make both cultural and subcultural schemas salient, which may conflict with one another even though they are both linked to the self (Brumbaugh, 2002).

Summary. In summary, research increasingly views categories as flexible representations. This flexibility has been demonstrated in research directed toward goal-derived categories, contextual influences on category structure, different self-views, and different cultural categories.

Activation of a Category Representation

Because much consumer knowledge can belong to multiple categories, it is important to understand factors that affect whether a specific category representation will be activated in a given situation.

When a consumer is exposed to information in an environment, a specific category representation may be activated, not activated, or even inhibited (see Macrae & Bodenhausen, 2000, for a more thorough discussion of activation of social categories). In the consumer psychology literature, evidence for accessibility generally includes measures of increased recall, increased use of the representation in subsequent judgments, and faster response times on either memory or judgment tasks. Priming of a category also increases its later use (Herr, 1989; Hoch & Ha, 1986; Yi, 1990), unless people are aware of the priming manipulation (Herr, 1989; Meyers-Levy & Sternthal, 1993).

In a branding context, Morrin (1999) analyzed whether exposing consumers to a hypothetical brand extension (e.g., Crest mouthwash) increased accessibility of the parent brand (e.g., Crest), as demonstrated by the speed with which the consumer indicated whether the parent brand was a member of the correct product category (e.g., toothpaste). The logic here is that if a person responds rapidly to a connection between Crest and toothpaste, then the brand extension (Crest mouthwash) also activates the parent brand (Crest) category. Morrin found that exposure to the brand extension increased accessibility of the parent brand, with the increase being less for typical than atypical brands in the category (e.g., Crest increasing less than Gleem in the toothpaste category). A prototypical brand (e.g., Crest) is already highly accessible in the context of its category (toothpaste), such that further increases in accessibility are unlikely to occur. In contrast, the atypical brand is not already accessible, such that exposure to it increased the parent brand's accessibility. Morrin also found that when the brand extension was a good fit for the brand category (e.g., breath mints, mouthwash, or dental floss), it increased the parent brand accessibility further (e.g., Gleem toothpaste), relative to when the brand extension was a poor fit (e.g., soft drinks, dishwashing liquid). Again, this facilitating effect occurred for the atypical brands (e.g., Gleem) more than for the typical brands (e.g., Crest). These effects replicate earlier consumer research indicating that prototypical category members are chronically more accessible than atypical category members (cf. Nedungadi & Hutchinson, 1985; Boush & Loken, 1991), and that priming a category increases its accessibility (Herr, 1989). In general, atypical category members stand to gain more from priming tasks.

A similar finding for accessibility and priming occurred in a different context, when ninth graders were primed with either cigarette ads or nonsmoking ads (Pechmann & Knight, 2002). Because most ninth graders have negative perceptions of smoking, anti-smoking beliefs should be chronically accessible whereas pro-smoking beliefs should not. Indeed, the authors found that priming pro-smoker beliefs (with cigarette ads) led to increases in pro-smoking responses (e.g., smoking intentions), whereas priming anti-smoker beliefs (with anti-smoking ads) led to no changes. Priming with both anti- and pro-smoking ads also led to no changes; the anti-smoking prime counteracted the pro-smoking one. Research in comparative advertising finds analogous effects. Specifically, comparative ads (showing a target brand along with a competitor) benefit an atypical brand such as Shasta cola, more than they benefit a typical brand such as Coke (e.g., see Grewal, Kavanor, Fern, Costley, & Barnes, 1997), and a comparative ad between an atypical brand and leading brand may benefit the atypical brand more than no comparison at all (Hutchinson et al., 1994). Priming a category has also been found to influence the type of processing in which consumers engage. Priming category information increases relational processing, or the extent to which consumers elaborate on the relationships or similarities between the category and the target object, relative to processing specific attribute information of the target object alone (Malaviya, Meyers-Levy, & Sternthal, 1999).

Research also suggests that perceptions of a category as accessible (i.e., easy rather than difficult to recall) influence category use (Schwarz, 2004). When people are asked to recall few (versus many) exemplars of a category (e.g., behaviors that increase one's risk of heart disease), they experience the exemplars as easy (rather than difficult) to retrieve and infer that the exemplars are more typical

(e.g., perceptions of heart disease risk increased, Rothman & Schwarz, 1998). Even imagined ease-of-retrieval influences judgments (Wanke, Bohner, & Jurkowitsch, 1997). In general, consumers utilize accessible experiences in evaluation and decision making, unless the relevance or information-value of these experiences is called into question (Schwarz, 2004). Consumer research on these meta-cognitive theories is increasing and provides an interesting focus for future research.

Modality-Specific Representations in Conceptual Processing: Where Do Categories Reside?

An important recent development in cognitive psychology is an increased empirical and theoretical interest in the interplay between cognitive systems (e.g., category representation) and the brain's modality-specific systems (e.g., for vision, action, affect) systems. In contrast to the traditional approach of viewing cognitive and modality-specific systems as functionally separate, recent research in cognitive psychology and cognitive neuroscience suggests that representations in modality-specific systems underlie conceptual knowledge (for reviews of relevant empirical findings, see Barsalou, 2003b; Barsalou, Niedenthal, Barbey, & Ruppert, 2003; Martin, 2001; Pecher & Zwaan, 2005). According to this view, the perceptions, actions, and mental states active while processing a category's members are captured in the respective modality-specific systems of the brain. For example, consumers' knowledge about colors is represented in their perceptual mechanisms that perceive and process colors; consumers' knowledge about sounds is represented in their perceptual systems that perceive and process sounds. Later, when representing a category in the absence of any members, the brain reenacts or "simulates" these perceptions, actions, and mental states. Barsalou (1999, 2003a) argues that these simulations can implement the central symbolic operations that underlie the human conceptual system, including categorical inference, the type-token distinction, predication, and conceptual combination. For example, in classifying a perceived category member, a simulation of the category is retrieved that is grounded in the modalities. In this way, the conceptual representation of a category (a modality-specific simulation) is similar to the perceived representation of the category, rather than being different (an amodal representation), thereby facilitating comparisons between them. Barsalou and Wiemer-Hastings (2005) further extend this approach to the representation of abstract concepts.

Prior consumer research. Consumer research is consistent with the view that modality-specific and conceptual systems are linked. Unnava, Agarwal, and Haugtvedt (1996) presented consumers with advertising information that was high in imagery-provoking ability (either high in visual imagery or high in auditory imagery) and then engaged them in a perceptual task involving either reading or listening to the information. They found that when mental images were activated, they competed with available cognitive resources if consumers were asked to perform perceptual processing in the same modality. The learning of visual information was reduced if the consumer read, rather than listened to, the information; the learning of auditory information was reduced if the consumer heard, rather than read, the information. Also, when information had high, rather than low, levels of visual imagery, it was learned better when it was presented auditorally, but less well when it was presented visually. These results provide support that imagery processing draws on the same mental resources as perceptual processing. Although imagery interferes with perceptual processing of the same modality (visual, auditory), generating visual imagery has been found to facilitate cognitive operations that are compatible with it. For example, visual images may serve as spatial representations (MacInnis & Price, 1987) that facilitate information processing. Along these lines, Keller and McGill (1994) found that visual imagery was effective when it was compatible with other aspects of the communication process. Attributes that were easy to imagine had more impact on judgments when consumers engaged in imagery processing than when they engaged in analytical processing.

Sometimes pictures can increase imagery and thereby spur processing. Information presented in a narrative format (e.g., stories) tends to be more effective than information presented in a disorganized list format, but only when accompanied by pictures or by instructions to image (Aval and Wyer, 1998). Similarly, narrative information is easier to process when it is physically integrated with relevant picture information, rather than being placed below it (Peracchio & Meyers-Levy, 1997). It seems clear that pictorial information is processed both perceptually and conceptually (e.g., Kim, Allen, & Kardes, 1996; Mothersbaugh, Huhmann, & Franke, 2002; Scott, 1994; Unnava, Agarwal, & Haugtvedt, 1996). Languages that rely on pictures or symbolic figures (logographic script) have been found to rely more on visual processes than languages based on alphabetic script (Schmitt, Pan, & Tavassoli, 1994; Tavassoli, 1999, 2001; Tavassoli & Han, 2001).

Type of imaging also influences the perceptual or cognitive processing in which consumers engage. Imaging and thinking about one's past experiences tends to produce more contextual details than anticipatory thinking about future events (Krishnamurthy & Sujun, 1999). Yet, when consumers were asked for information relevant to designing new products, they produced more innovative and effective information when imaging new uses for the product (anticipatory) than when thinking about past experiences, which limited visualization to retrieved memories (Dahl, Chattopadhyay, & Gorn, 1999).

Summary and Future Research

Research on category representations is increasingly focused on the flexibility associated with goal-derived and other types of categories, and we anticipate this focus to continue in consumer research. Also, although the literature covers category activation rather extensively, category inhibition has been less thoroughly considered (e.g., Macrae & Bodenhausen, 2000). For example, the question of how consumers become cognizant of stereotypical (categorical) bias and then correct for it (e.g., stop unwanted thoughts) are both newer areas of research.

Finally, new research on the link between modality-specific and cognitive processing in categorical representations is a promising new direction for researchers. Consumer research shows a strong link between conceptual and modality-specific systems in the brain. Perception, imagery, and higher cognition, share representational mechanisms. Pictures tend to facilitate imagery as well as to facilitate cognitive processing. The quality of imagining (e.g., anticipating the future versus reflecting on past experiences) also influences the specific objects and events that are processed. Future research could examine the links between conceptual and modality-specific systems within particular modalities (e.g., touch, smell, taste, action) not previously examined in consumer psychology, and also in the context of different types of consumer categories (e.g., perception of brand categories and goal-derived consumer categories). Further research based on the nature of specific descriptive and affect-laden information associated with this link would also be worthwhile.

In addition to uncovering interesting findings about category representations in the previous two decades, consumer research on category-based inferences has also increased dramatically. In the next section, we examine this research, the second major topic addressed in this chapter.

SIMILARITY-BASED CATEGORY INFERENCE: THE INFLUENCE OF A CATEGORY ON A NEW CATEGORY MEMBER

A primary reason category information is useful to consumers is that it can be used in making judgments about new category members, which are traditionally referred to as *category inferences* or *inductions*. Much of the consumer research on category inferences has been performed with

brand categories, examining the extent to which beliefs (and affect) associated with a brand category are used to draw inferences about a new brand extension. Although many other marketing categories are relevant, this focus on brand categories is understandable. Marketing practitioners often manage their companies' products as brand categories; many companies are organized by brands. Given the continuing popularity, for a variety of economic and strategic reasons, of brand leveraging strategies (e.g., brand and line extensions, licensing) the number of products associated with many brand names has continued to grow. As a result of this, it is common to see new products launched with existing brand names and increasingly, the promotion of the full range of products under a brand name in a single communication. In this environment, consumers will be more inclined to think about brands as categories when considering new products introduced with an existing brand name, when considering the specific image or evaluating a particular brand name (Loken, Joiner, & Peck, 2002), or when attending to marketing communications for an existing brand and product. In this literature, a typical research scenario is one that examines the extent to which brand category inferences extend from the original brand category (e.g., Lexus) to a new brand extension (e.g., Lexus Hybrid, usually a hypothetical extension of the brand). Measuring the extent to which the new extension is similar to the brand category is the most standard approach for determining whether these inferences will occur. For example, in learning about the new Lexus Hybrid, consumers may infer that it shares similarities with both the traditional Lexus (e.g., high performance, prestige, and leather seats) as well as other hybrid automobiles (e.g., good for the environment, high gas mileage, and expensive).

A key factor that determines whether category inferences are extended in this manner is the similarity or match between the representation of the brand category and the representation of the new brand extension. Consumers use prior knowledge about the category and the new category member to judge the relationship between them. When the relationship is perceived to be high, inferences are likely to be drawn from the category to the new member. When a new category member is viewed as dissimilar from the category, the relevance of category information is diminished, decreasing belief and the transfer of affect.

In the sections that follow, we review findings that affect the perceived similarity of two categories in the context of induction. In addition to the important role of prior knowledge about categories, we examine two other consumer psychological factors that affect perceived similarity: accessibility and relevance. Consumers selectively attend to only a subset of knowledge available about the category and the category extension, and this selective focus is influenced by: (a) the accessibility of information either retrieved from memory or in the environment, and (b) the relevance of information in achieving specific goals. In contexts that include both brand and product categories, researchers have also examined the alignability of attributes and the circumstances that increase contrast effects (rather than assimilation to the category). In the sections that follow, we review how these various factors affect category inferences.

Accessibility and Similarity-Based Inferences

Brand category accessibility and similarity-based inferences. The accessibility (or salience) of information pertains to the ease with which category information is retrieved from memory, or the ease with which it is perceived in the environment. A brand category, such as Snickers, can be viewed as consisting of a set of brand attributes (e.g., peanuts, chocolatey, tastes good), or as a set of exemplar products (e.g., Snickers candy bars, Snickers miniatures, Snickers ice cream bars), or both. In any given context, information about either brand attributes or exemplar products of a brand, or both, may vary widely in accessibility, with some being much more accessible than others (Loken,

Joiner, & Peck, 2002; Meyvis & Janiszewski, 2004). The highly accessible information for a new category member (e.g., Snickers ice cream topping) may include its product category (ice cream topping), its brand name (Snickers), its connection to the brand name (e.g., strong or weak connection), and/or its individuating attributes (e.g., its texture when used as a topping for ice cream is creamy). Increasing the salience of specific attributes can have a very strong effect on category membership judgments and processing of new brands (Hutchinson & Alba, 1991). When accessible information about the brand category and accessible information about the brand extension are similar, category inferences are more likely to occur. An abundance of research supports the idea that the properties of the brand category (e.g., cognitions and affect regarding the brand Snickers) transfer to the properties of new exemplars (brand extensions such as “Snickers ice cream topping”), to a greater extent as the perceived similarity between the brand category and the brand extension increases (Aaker & Keller, 1990; Bottomley & Holden, 2001; Boush & Loken, 1991; Boush et al., 1987; Hansen & Hem, 2004; Zhang & Sood, 2002).

Research also demonstrates that changing the focus of the similarity comparison often changes the perception of similarity between the two representations. Depending on what type of information is accessible and/or selectively attended to about the brand (brand image attributes; product categories of the brand) or about the extension (product category of the extension; individuating information; relationship-to-category information), similarity judgments can vary widely. For example, Lane (2000) found that when consumers were exposed repeatedly (five times) to information about a new brand extension, and that when the information focused on the extension’s positive connection to the brand, people’s perceptions of extension similarity increased relative to a single-exposure condition. The key mechanism that produced this change was an increase in positive thoughts about the extension as exposure increased. This effect even occurred when the exposure information included brand associations not strongly related to the brand. Just focusing on positive attributes of these peripheral associations was sufficient to trigger positive thoughts about the extension. In general, repeated exposure directed the focus of attention, the focus of elaboration, and consequently the inferences that consumers made about an extension, leading to an increasingly positive evaluation. Klink and Smith (2001) found, too, that multiple exposures (three versus one) increased the acceptance of a moderately dissimilar extension, in this case when only the brand name and extension category information were provided. Lane (2000) found, however, that when the extensions were highly dissimilar to the brand category, and when the ad evoked associations that were not strongly related to the brand, repeated exposure did not lead to more acceptance of the extensions.

Meyvis and Janiszewski (2004) found that properties of the brand category, specifically whether it included a narrow or broad array of products, influenced the type of information to which consumers selectively attended. They reasoned that narrow categories (e.g., a brand such as Campbell’s, which makes mostly soups) will have accessible associations that include the product category (soup), more often than will broad categories (e.g., Healthy Choice, which makes a variety of products), for whom product category associations are more diffuse and weaker (cf. Boush & Loken, 1991). The product category associations of narrow (versus broad) brands (e.g., soup) are therefore stronger and more likely to compete and interfere with associations pertaining to brand image attributes (e.g., tastes good). When assessing new brand extensions, the narrow brand focus is more likely to include product category information (e.g., soup) as a basis for similarity perceptions, leading to greater acceptance of close category extensions (e.g., new soups) and lower acceptance of far category extensions. The broad brand, in contrast, for which product category associations are weaker and brand attribute associations are stronger, leads consumers to show less extreme responses to close and far extensions, and more acceptance as a function of

whether the brand attributes are broadly similar (e.g., do the brand attributes transfer easily to the new extension?).

Finally, Klink and Smith (2001) found that when individuating attribute information is available, it can become the focus and reduce the emphasis on the parent brand category and on its relationship to the extension. Specifically, the effects of brand similarity on extension evaluations diminished when individuating information conveying novel features for the extension (e.g., Timex bicycle and a unique gear system) was accessible.

Brand name accessibility and similarity-based inferences. In the same way that narrow (versus broad) brands trigger specific (versus general) category associations, the *name* of a brand can vary in whether it triggers specific (or general) category associations and/or specific (or general) brand attribute associations. Keller, Heckler, and Houston (1998), for example, found that the name of a new extension was remembered better when it suggested superiority on a specific brand attribute (e.g., PicturePerfect televisions), than when it suggested superiority on a general attribute (e.g., Emporium). Focusing on a specific attribute of a brand can also diminish the emphasis placed by the consumer on the brand category (and its broad array of attributes), but it can also diminish consumers' acceptance of new brand extensions (van Osselaer & Alba, 2003). For example, the specific (versus general) name inhibited memory for brand attributes unrelated to the specific attributes.

Co-branding strategies and similarity-based inferences. When two brands are combined in a co-branding strategy (e.g., Slimfast chocolate cake mix by Godiva) or brand alliance (e.g., Northwest Airlines and Visa), associations of each brand category, as well as the relationship between the two brands, may be triggered. Park, Jun, and Shocker (1996) found that a co-branded extension (e.g., Slimfast chocolate cake mix by Godiva) led to more favorable attribute inferences when the header brand (Slimfast) was combined with a complementary brand (Godiva) than when combined with a noncomplementary brand (e.g., Haagen-Dazs). Complementary brands were those that contributed along attribute dimensions that the other brand lacked. Also, complementarity of brands was more effective in benefiting the co-branded extensions than simply combining two equally favorable brands. In addition, because a co-branded (versus monobrand) extension creates the perception of difference between a parent brand and the brand extension, countermoves made by a competitor in response to the extension are perceived less favorably (Kumar, 2005).

However, co-branding with two well-known brand names also increases consumers' expectations for the co-branded product. For example, ingredient branding using a well-known brand name weakened brand quality inferences because of overexpectations, an outcome described by van Osselaer and Janiszewski (2001) in terms of connectionist models of adaptive learning (also, van Osselaer & Alba, 2000).

When two brands are combined, and when consumers are more familiar with one than with the other, consumers' inferences from one brand to the other are unidirectional, from the familiar to the unfamiliar brand (Simonin & Ruth, 1998). Similarly, when two (hypothetical) restaurants are linked, and only one of the restaurants is well defined, the well-defined brand restaurant serves as a context for making inferences about the ambiguously-defined restaurant (Levin & Levin, 2000).

Relevance to a Specific Consumer Goal

As noted earlier, when a specific goal is salient, exemplars that accomplish the same goal will be perceived as more similar than exemplars that are physically similar but do not accomplish the same goal (Ratneshwar, Barsalou, Pechmann, & Moore, 2001). Furthermore, goal-relevant information is more likely than goal-irrelevant information to be used during comparison judgments when evaluating a new category exemplar. In the context of brand categories, consumers generate

increasingly positive category inferences about a new brand extension as the perceived similarity between the extension and the parent brand on “image” and other goal-related attributes of the brand increases (e.g., Park, Milberg, & Lawson, 1991; see also Chakravarti, MacInnis, & Nakamoto, 1990; Herr, Farquhar, & Fazio, 1996; Keller & Aaker, 1992; Smith & Park, 1992). Consumers also generate more positive inferences as the perceived relevance of the brand’s attributes to the new extension increases (Broniarczyk & Alba, 1994).

Broniarczyk and Alba (1994) found that even when an extension is in a dissimilar product category, it can be viewed as acceptable if the attributes of the brand category are relevant to the new extension. The Ralph Lauren brand image, for example, has transferred successfully to product categories that are low in physical similarity to its core product base of apparel (e.g., perfume, paint), but that share a prestige image of the brand. An extension that is physically similar to a parent brand product (e.g., Nike dress leather shoes), but that is incongruent with the brand category’s goals, may not be successful. Martin and Stewart (2001) found that when an extension is moderately incongruent with the goals of the parent brand category, the attitudes toward the category have less impact on attitudes toward the brand extension (and purchase intent) than when the extension is congruent with the goals of the parent brand category. When the extension was extremely goal-incongruent, the attitudes toward the parent brand category had no impact on attitude toward the extension (or purchase intent). Further, when two products shared a set of goals, consumers’ elaborations about those products were more detailed and focused on a link between attributes of the extension and the parent brand. When two products were less goal-congruent, consumers’ elaborations about them were less detailed and focused on why the extension was not a good fit. Finally, Martin and Stewart (2001) found that when both product category similarity and brand attribute similarity reflected a common goal, they both predicted extension acceptance. If the consumer had multiple goals that were incongruent with one another, then other factors, such as a similarity heuristic, predicted extension acceptance (Martin & Stewart, 2001).

Similarity as a Heuristic

Using categorical information often simplifies judgment and decision-making, because consumers produce useful inferences by comparing current information about a perceived product to relevant category information. Similarity between a parent brand and an extension has also been viewed as a heuristic used in making extension-related judgments under certain conditions. For example, category inferences that simplify decision-making (e.g., evaluation-based inferences, similarity-based inferences, and correlational rules) are more likely to occur when cognitive resources are low, when people are unmotivated to process detailed information, when they lack the ability to do so, when the category information is sufficiently relevant and accessible for use, or when there is no sufficient justification for accuracy in judgment (e.g., Alba & Hutchinson, 1987; Alba, Broniarczyk, Shimp, & Urbany, 1994; Maheswaran 1994). In contrast, when resources, ability, and/or motivation are abundant, people are more likely to elaborate more on the details of the new category member and its idiosyncrasies.

In their research examining consumers’ classification learning, Hutchinson and Alba (1991) distinguished between analytic and holistic processing. Analytic processing was operationalized as those categorization decisions that were based exclusively on features diagnostic of category membership (i.e., “criterial” attributes). Nonanalytic or “holistic” classification was operationalized as those involving membership decisions based on overall brand similarity. Hutchinson and Alba (1991) found that perceptual salience of attributes enhanced analytic learning if the attributes were criterial but inhibited learning if they were not. Both analytic and nonanalytic processing tended to

be multiattribute in nature, but nonanalytic processing was limited to a smaller subset of available attribute information as compared with analytic processing.

Research further suggests that similarity is used as a heuristic when similarity information is accessible and when more relevant information is unavailable. For example, when the relationship between the category and the new category member is made accessible through repeated exposure, increased elaboration, or instructions to elaborate on relations between them, similarity will be more likely to be used as a heuristic (and when other information is not accessible). As noted earlier, similarity was used when product category information about the parent brand (Meyvis & Janiszewski, 2004), or product category information about the brand extension (Klink & Smith, 2001), was the only information available or accessible to the consumer. When individuating information about the brand extension was available, the individuating information, rather than a similarity heuristic, was used (Klink & Smith, 2001).

Alignability of Attributes

Another type of similarity-based comparison, generally studied outside the domain of brand categories, involves the alignability of attributes between the new category stimulus and the existing category representation in memory (Gentner & Markman, 1997; in the consumer literature, Gregan-Paxton, 2001; Moreau, Lehmann, & Markman, 2001; Roehm & Sternthal, 2001). Alignable differences focus on the structural properties of attributes and the degree to which attributes from one object can be “mapped onto” another object. Research finds that alignable differences (versus differences that are not alignable) are more accessible from memory (Zhang & Markman, 1998), are perceived as more useful inputs in judgments (Markman & Medin, 1995; Zhang & Fitzsimons, 1999), and increase brand evaluations in comparative advertising (Zhang, Kardes, & Cronley, 2002). When two different brands were paired in a comparative advertising setting, the more the attributes of the target brand could be mapped onto (or compared with) those of the comparison brand, the higher the target brand evaluations (Zhang, Kardes, & Cronley, 2002). When two brands were not alignable, the brands were more difficult to compare, and transfer of affect was less likely to occur.

Assimilation and Contrast in Consumer Contexts

The research on similarity-based inferences finds that the lower the similarity between the new category and an existing category, the lower the likelihood of category-based inferences. Assimilation and contrast theories in psychology (e.g., Herr, Sherman, & Fazio, 1983; Martin, 1986; Mussweiler, 2003; Schwarz & Bless, 1992) make a different set of predictions. They suggest that if, at encoding, the domains or categories for the context and target match (or are at least similar), assimilation will likely occur, and there will be a positive transfer of beliefs between the two. These theories suggest that the assimilation of information to a target results under conditions in which the information is included in a temporary representation of the target, whereas contrast effects result from exclusion of the information from the representation, and the use of the target as a standard of comparison from which to judge the information (Schwarz & Bless, 1992). When the similarity between the new instance and the existing category are high, an assimilation effect occurs, such that beliefs and affect are more likely to transfer to the new instance. But conditions that produce contrast effects show how the theories are different from theory and research discussed earlier that predict category-based inferences. In particular, under certain conditions, consumers' judgments show contrast effects for extremely dissimilar (atypical) category instances. In these cases, not only may

beliefs fail to transfer from a familiar brand (Ralph Lauren) to an extremely atypical new brand extension (Ralph Lauren toaster oven), but contrast effects may produce a negative impact of the brand on the new product (evaluations and beliefs about the toaster oven may be *more* negative as a result of the brand name). Seemingly, category information should be viewed as irrelevant for judgments about a new category member that is extremely atypical, or when people are skeptical that an atypical instance is a category member. For example, a consumer may simply discount the Ralph Lauren toaster oven as an anomaly. If so, atypical instances should not affect category perceptions, and category knowledge should not be used to form inferences about the atypical instance (Fiske & Neuberg, 1990). As Wanke, Bless, and Schwarz (1998) suggest, however, if an atypical instance is perceived as excluded from the target category (the toaster oven is not included in the Ralph Lauren brand category), then judgments pertaining to it may reflect contrast effects (see, also, Stapel, Koomen, & Velthuisen, 1998, for an alternative explanation for contrast effects).

Research finds some evidence for contrast effects. In the consumer domain, researchers have attempted to determine the conditions under which advertising information will be assimilated versus used as a standard of comparison and contrasted with the target category or representation. Assimilation effects, viewed as the default, occur more often than contrast effects, and are more likely to occur under conditions of category or domain similarity. Contrast effects are more likely under conditions of category or domain mismatch or dissimilarity (Hafner, 2004; Mussweiler, 2003). Contrast effects are also likely when substantial cognitive resources are available for processing comparison information (Meyers-Levy & Sternthal, 1993), when the individuals are high (versus low) in need for cognition (Meyers-Levy & Tybout, 1997), when remembered information is recounted analytically, rather than episodically (Bickart & Schwarz, 2001), and when situational cues include dissimilarities, rather than similarities (Hafner, 2004).

SUMMARY AND FUTURE RESEARCH

In sum, research shows that the degree to which inferences from a category are extended to a new category member reflects three factors: (1) What information is accessible? As information that triggers similarity associations between the brand category and new brand extension becomes more accessible, the greater the likelihood that category inferences are drawn (e.g., when product category information is the only information available; when the relationship between the brand category and new brand category member is salient; when attributes of the extension are the same as the category's attributes). (2) Is the accessible information appropriate? If accessible information pertains to the category in which an object is being judged, then that information will probably be viewed as relevant or appropriate. (3) What information is elaborated upon? To the extent that elaboration (e.g., due to repeated exposure to the extension) increases the perception that a connection exists between the category and extension, similarity-based inferences are more likely to occur.

Future research could analyze how similarity or typicality relations benefit from frequency (e.g., Barsalou, Huttenlocker, & Lamberts, 1998) apart from feature similarity. Future research could also examine how category inferences are influenced by the number and typicality of exemplars retrieved when a category judgment is made. In a context in which a larger number of exemplars, or a broader array of exemplars, is retrieved, consumers may be more confident in making inferences based on those exemplars than in a context in which a small number of exemplars, or a narrower array of exemplars, is retrieved. Individual differences may also exist in sampling exemplars from memory, such that some consumers retrieve more representative exemplars than other consumers, due to motivational, ability, and contextual factors.

A factor that could influence the perceived relevance of category information is the degree to which category information is stable or unstable for a given individual. When the same representations (e.g., prototypes, exemplars) are retrieved across multiple occasions and contexts (cf. Lord, Paulson, Sia, Thomas, & Lepper, 2004), the stability of these representations may facilitate category inferences that lead to more stable beliefs and attitudes, as compared with exemplars that are unstable or vary significantly across occasions and contexts. Also, when a consumer retrieves and uses unstable exemplars as bases for an attitude toward a category, that category attitude may be more vulnerable or susceptible to change. On the other hand, such attitudes, because they are based on unstable or changing exemplars, may be more flexible and less rigid in the face of disconfirming information.

THE INFLUENCE OF NEW CATEGORY MEMBERS ON EXISTING CATEGORY REPRESENTATIONS

Not only can category knowledge be used to make inferences about new category members, the reverse flow of influence can also occur. Information about new category members can influence existing category beliefs and attitudes, and thereby alter the representation of the existing category.

Brand Categories and New-Member Effects

In the consumer psychology literature, these new-member effects have been examined chiefly in the context of brand categories, where they can either have a positive (enhancement) effect or a negative (dilution) effect on people's general beliefs about the category. Loken and John (1993) examined whether information about a new inconsistent category member (brand extension) influenced beliefs about the brand category negatively. They found that, for the brand category Johnson & Johnson, negative information about a brand extension's gentleness rating influenced consumers' beliefs about both the extension and the general category, that is, the parent brand Johnson & Johnson.

John, Loken, and Joiner (1998) found that, in addition to affecting the parent brand category negatively, a moderately inconsistent brand extension can influence consumers' beliefs about prior existing products of the brand. For example, a new Johnson & Johnson brand extension (e.g., hand lotion) that was rated low on the gentleness attribute impacted consumers' beliefs about the parent brand, Johnson & Johnson, as well as beliefs about prior existing exemplars of the brand (e.g., Johnson & Johnson dental floss). Interestingly, Johnson & Johnson's flagship product, Johnson & Johnson baby shampoo, was most immune from dilution effects, presumably because gentleness beliefs about this product were firmly established and more resistant to change.

A key factor that determines extent of dilution is the similarity between the parent and new brand extension, or, alternatively, the perceived typicality of the new brand extension of the parent brand category. Milberg, Park, and McCarthy (1997) found that the more the brand extension was either inconsistent with the parent brand image or dissimilar from the parent brand's product categories, the greater the amount of dilution (i.e., negative transfer of association from the extension to the brand category). However, negative information had no effect on parent brand beliefs when the extension was viewed as extremely atypical and these atypical perceptions were salient (Loken & John, 1993), or when the extension was introduced using a sub-branding strategy (Milberg, Park, & McCarthy, 1997). These *modified* dilution effects are consistent with prior research in social categorization (Rothbart & Lewis, 1988). A moderately inconsistent brand extension (e.g., a Johnson

& Johnson facial tissue that was rated low on the gentleness attribute) was viewed as moderately atypical of the parent brand (Johnson & Johnson). An extremely inconsistent brand extension (e.g., a Johnson & Johnson facial tissue that was rated low on *both* gentleness and quality attributes) was viewed as extremely atypical of the parent brand. When these typicality judgments were made salient, consumers used them in forming judgments about the parent brand, such that moderately atypical extensions had a negative effect on the parent brand beliefs and extremely atypical extensions had no effect (cf. Rothbart & Lewis, 1988). Thus, people appear to discount inconsistent extension information when the extension is viewed as extremely inconsistent (versus moderately inconsistent) of the category and, importantly, the atypicality (or typicality) of the extension is salient (Loken & John, 1993). In a different applied domain, within U.S. culture, beliefs about social reality (e.g., occupational categories) have been shown to be caused in part by television viewing, especially among heavier viewers, who failed to discount TV-based exemplars in forming their beliefs (Shrum, Wyer, & O'Guinn, 1998), perhaps because these exemplars are moderately, but not extremely, inconsistent with prior category beliefs.

The dilution effects of Loken and John (1993), as well as positive extension effects on the brand (brand enhancement), were replicated by Gurhan-Canli and Maheswaran (1998) under conditions of high motivation, when people were more likely to use detailed, thoughtful processing to evaluate the brand category and its members. Under low motivation, the modified, heuristic-based dilution effects of Loken and John were replicated; that is, more (versus less) typical extensions diluted the parent brand evaluations. According to the authors, people used less analytical processing (Gurhan-Canli & Maheswaran, 1998), and the Rothbart and Lewis predictions applied.

In a follow-up study of brand enhancement and dilution, Ahluwalia and Gurhan-Canli (2000) predicted that negative information would be more diagnostic than positive information when evaluating close (typical) new brand extensions, but that positive information would be more diagnostic than negative information when evaluating far (atypical) brand extensions. Ahluwalia and Gurhan-Canli also predicted, however, that these effects would occur only when other relevant brand extension information was not accessible. Results of their research were supportive. When brand extension information was highly accessible, positive extension information created more positive parent brand category evaluations, and negative extension information created more negative parent brand category evaluations. When extension information was lower in accessibility, negative extension information induced dilution effects for close (but not far) categories, and positive information induced enhancement effects for far (but not close) categories, supporting the idea that negative information is more diagnostic for close (versus far) categories, whereas positive information is more diagnostic for far (versus close) categories.

The brand extension literature illustrates the conditions under which moderately typical but not extremely atypical extensions will impact parent brand beliefs. In these conditions, when typicality information is salient or accessible, extremely inconsistent brand extensions are viewed as implausible, or exceptions, and their information content is discounted.

Employees of a Firm and New-Member Effects

Folkes and Patrick (2003) reported analogous findings when the employees of a firm were the category members being evaluated. Negative information about a particular service employee was less diagnostic about other employees of the same firm when that service employee was viewed as atypical of the company overall. In these cases, information about the employee was discounted in evaluating the service category as a whole. Positive information about an atypical employee, however, did have an effect (and more effect than negative information) on evaluations of a related

subgroup in the firm. Matta and Folkes (2005), too, demonstrate more discounting of information about atypical than typical employees of service providers, and further demonstrate that employing a positively-rated atypical provider increased brand differentiation (i.e., the perception that the firm was different from competing firms) compared with those employing a positively-rated typical provider.

Summary and Future Research

The literature on brand extensions has provided much insight into the possible influence a new category member can have on the overall category, and also on individual category exemplars. First, researchers have assessed when new category members will affect the category's representation. Empirical findings show that they affect it when they are viewed as at least somewhat typical of the category. If they are viewed as very atypical, then information about the new category member is discounted, and has no effect on the category. The diagnosticity of the atypical new category member varies depending on how related it is to the category, whether the information about the new category member is positive/negative, and the extent to which the information is accessible. Brand extension research has also demonstrated that a new category member can influence beliefs or evaluations of a particular existing category member, but that central category members (e.g., flagship products) are least vulnerable to change.

Additional areas to be examined in the future include developing a better understanding of the potential impact a new member has on individual category members. For example, what factors influence the diagnosticity of this information? Does diagnosticity reflect the characteristics of the existing category member (e.g., familiarity, strength of beliefs, linkage to the category) or of the new category member (e.g., plausibility of the information, confidence in the information, knowledge of the product category, salience of category membership) or of some other factor (e.g., availability of competitor information). Future research could also explore the conditions that make category membership appear relevant to the task. Does relevance depend on subjective experiences of the consumer, or on some form of meta-cognition?

Having considered the roles that similarity and related processes play in category-based inferences, we next turn to literature that addresses how similarity-based processes contribute to the flexibility of category structure described earlier.

FACTORS THAT INFLUENCE CATEGORY FLEXIBILITY AND EXPANSION

As described earlier, category representations are characterized by a degree of flexibility and expansiveness. In addition to the flexibility of category boundaries and category membership demonstrated through goal-derived category research, a number of motivational, ability, and contextual factors have been found to increase category expansiveness, usually by changing perceptions of category similarity. Emotional states, discussed next, are an example of motivational states that influence category flexibility.

Emotional States

A positive mood state has been found to increase category flexibility (Isen & Daubman, 1984). In the consumer psychology literature, researchers have found that people in a positive mood showed increased relational elaboration (elaborating on the interrelationship between items), which included greater clustering of brands by product category membership, greater recall of brand

names when they were in the same categories as stimulus brands (Lee & Sternthal, 1999), increased categorization of nontypical items as belonging to a category, and increased optimism about the success of a stimulus product (Kahn & Isen, 1993).

Barone and Miniard (2002; Barone, Miniard, & Romeo, 2000) showed positive mood effects on category flexibility in the context of brand categories. Specifically, they suggested that increased flexibility might consist of rating moderately dissimilar extensions (e.g., Nike basketball nets) as more acceptable under certain affective conditions. When consumers were in a positive mood (relative to a negative mood), and when they received information about a new category member (brand extension), they were more likely to transfer positive evaluations from the category (parent brand) to the new category member (brand extension), even if the new category member (brand extension) was moderately dissimilar from the category (parent brand) attributes (Barone & Miniard, 2002; Barone et al., 2000). The categories of people in a negative mood were more rigid. These researchers also examined extensions in very similar and extremely dissimilar categories. The category flexibility of people in a positive mood did *not* occur when the membership of a category exemplar was viewed as implausible (e.g., for a distant, extremely dissimilar extension), and was not needed when the categories were highly similar (e.g., for near extensions).

Another motivational variable found to influence willingness to expand category boundaries is a person's feelings of commitment to the category. For example, a study done among South Korean homemakers (Park, Kim, & Kim, 2002) found that feeling trust and commitment toward a brand increased the acceptability of an extension when the attribute claims of the extension were atypical (versus typical) of the brand category, as long as the extension product category was not too dissimilar from the category.

Expertise

Expertise in a domain is an ability factor that has been found to increase flexibility in categorization. Cowley and Mitchell (2003) found that experts (relative to novices) were more likely to organize information by product subcategories, and to store information about alternatives in a way that increased flexibility when evaluating the same product across different usage occasions (Mitchell & Dacin, 1996), or when retrieving different brands for different usage occasions (Cowley & Mitchell, 2003). Owners (versus nonowners) of a brand were more likely to accept brand extensions that "stretch" a nonprestige brand's price line upward or downward, and that stretch prestige brands upward (e.g., American Express platinum card; Kirmani, Sood, & Bridges, 1999). Owners were less accepting of downward stretches of prestige brands (e.g., a new BMW for \$11,990), because of owners' preferences for brand exclusivity, such that a sub-branding strategy (e.g., Ultra by BMW) was preferred.

Cognitive psychologists have argued further that, early during the development of expertise in a domain, conceptual knowledge increases the salience or importance of certain perceptual distinctions. Perceptual knowledge serves as the data to which conceptual theories originally pertain (Barsalou, 1999; Smith & Heise, 1992). As people's expertise increases, so does their ability to attend selectively to perceptual aspects that are relevant to precise categorization (Johnson & Mervis, 1997). In other words, experts are not simply able to think more abstractly conceptually. Their knowledge allows them to attentionally select increasingly subtle perceptual distinctions relevant to categorization (Johnson & Mervis, 1997).

Further research has found that teaching consumers strategies can increase their ability to process categories flexibly. For example, when consumers were taught decompositional strategies (e.g.,

unbundling credit card expenses into different subcategories), they exhibited both increased accessibility of information and reduced biases in memory and estimation (e.g., Menon, 1997; Srivastava & Raghurir, 2002).

Coverage/Diversity of Category Members

As noted earlier, brand names can be suggestive of broad or narrow categories. When an ingredient in a brand was branded (e.g., Tide with Irish Spring scent), and the change to the brand was relatively minor, consumers were more likely to accept the brand extension in the short-term. Using a new ingredient name (e.g., Tide with EverFresh scent), however, improved long-range expansion into new product categories (Desai & Keller, 2002). The exception to this effect is when the ingredient represented a significant attribute change. Under these conditions, the extension fares better when the ingredient is co-branded than when it has a new name, conceivably because the branded ingredient enables consumers to view the brand extension as a plausible extension (assuming that the brand connection to the ingredient is credible). In these cases, the branded ingredient provided additional associations that the existing brand did not originally possess (i.e., broadening the brand category), which proved beneficial in the new category. More diverse or broad categories (as compared to narrow categories) also have brand associations that allow for a broader range of new acceptable category exemplars to which parent category affect and associations can be assimilated (Boush & Loken 1991).

Brand diversity or coverage also explains why sequential brand strategies can increase brand acceptance over a nonsequential strategy (Dawar & Anderson, 1994; Keller & Aaker, 1992). Introducing new category members in a sequential strategy (i.e., moving from products that are more to less similar), increases the likelihood that extension categories will be viewed as moderately rather than extremely dissimilar, thereby increasing the chances of consumer acceptance. For example, if a brand category that makes only cameras moves into cell phones, consumers would view this product extension as more dissimilar to the brand than if the brand had instead initially introduced camera cell phones followed by regular cell phones. When Ralph Lauren expanded their product line to designer paints, they followed a sequential strategy that flowed from designer apparel to designer bedding (and home furnishings) to designer wall coverings (including paints), rather than moving directly from designer apparel to designer paints. A sequential expansion that progresses to more and more dissimilar categories slowly increases perceptions of brand coverage, which in turn increases perceptions of similarity and brand extension acceptance. A nonsequential strategy does not have these benefits, as the perception of similarity is too implausible for the perceiver, such that they reject the new extension. According to Osherson, Smith, Wilkie, Lopez, and Shafir's (1990) similarity-coverage model, premises from diverse categories that exhibit greater coverage lead to stronger arguments than premises from categories that are very similar to one another.

Diversity per se (i.e., having a greater number of products under the parent brand umbrella), however, does not translate into greater consumer confidence in the brand (Dacin & Smith, 1994). Sometimes diversity leads to uncertainty about category attributes. Folkes and Patrick (2003), for example, found that inferences from one category member to other category members were less likely to occur when the category members were heterogeneous than when they were homogeneous.

PROTOTYPICALITY AND AFFECT: HOW ARE THEY RELATED?

In addition to flexibility, another characteristic of categories that has been widely researched is the concept of graded membership. Many models of category representation suggest that membership

is graded, with members ranging from very good (typical) members of the category to very poor (atypical) members of the category. One reason that this characteristic has been researched extensively in consumer psychology is because of its relationship to affect. For example, first movers in a consumer category are generally thought to have advantages of category prototypes such as being preferred to second or third movers in the category (Carpenter & Nakamoto, 1989).

In this section we present an overview of the relationship between prototypicality and affect, and we address the significance of this relationship in consumer research. Many studies in consumer psychology have reported a positive relationship between the prototypicality of a category member and the evaluation or attitude associated with it. For example, Loken and Ward (1990) found that, although the correlations between typicality and attitude ranged from .00 to .92 for 16 different product categories, it was positive and significant overall across the 16 categories ($r = .58$, $p < .01$). More typical items were better liked. For instance, among fast food outlets, the more prototypical ones (e.g., McDonald's) tended to be more preferred or better liked relative to less typical ones (e.g., Church's Chicken or Taco Bell). Other research, too, supports a positive, linear relationship between prototypicality and attitude (Carpenter & Nakamoto, 1996; Folkes & Patrick, 2003; Simonin & Ruth, 1998; Veryzer & Hutchinson, 1998).

Several explanations have been offered for this linear relationship. One explanation is based on the concept of perceptual fluency. By this account, more typical members of a category also tend to have greater perceptual fluency, which is affectively pleasing (e.g., Schwarz, 2004). Perceptual fluency increases over time, as familiarity with a stimulus increases. A related concept is frequency of instantiation, or the frequency with which an item appears as an instance of the category (Barsalou, 1985). Researchers have found that both the extent to which a category member is instantiated, and also the person's perceived familiarity with the category member, are significant predictors of category member typicality, and also tend to predict attitudes toward the category (e.g., Barsalou, 1985; Loken & Ward, 1990; Viswanathan & Childers, 1999).

A second explanation for this linear relationship is that typical category members are more likely than atypical category members to have valued attributes, as the category has evolved over time (Loken & Ward, 1990). New category members tend to include attributes that are valued by consumers, and these attributes tend to overlap with attributes that are more common for typical than for atypical category members. If the value of attributes underlies this relationship, then categories with negatively valued attributes should show the opposite effect, and they do (Ward & Loken 1988). This explanation might also explain why earlier research on taxonomic categories did not find a positive relationship between typicality and attitude (Rosch, 1973). Because some categories had a positive relationship and other categories had a negative relationship, these patterns averaged to zero.

In the context of brand categories, as noted earlier, new category members (new brand extensions) are better liked when they are similar to, or typical of, the parent brand (Aaker & Keller, 1990; Boush & Loken, 1991; Boush et al., 1987; Broniarczyk & Alba, 1994; Zhang & Sood, 2002; see also, Chakravarti, MacInnis, & Nakamoto, 1990; Herr, Farquhar, & Fazio, 1996; Keller & Aaker, 1992; Park, Milberg, & Lawson, 1991; Smith & Park, 1992). Hence, in this context, too, greater typicality is related to more positive affect. While the nature of the criteria used for establishing similarity, typicality, or "fit" between the new extension and the parent brand varies for these studies, the conclusion is the same: In the absence of any relevant negative information about the brand extension, a greater fit contributes to more acceptance and stronger affect toward the new extension. In these studies, the brand categories examined were ones associated most with positive (rather than negative) features.

Aesthetic product design evaluations, in addition to being influenced by prototypicality, are also influenced by whether the visual elements of the design appear to belong together in a unified or Gestalt-like fashion (Veryzer & Hutchinson, 1998). In an advertising context, when the components of a communication process are congruent and seem to belong together, people's attitudes toward the brand increase (Kirmani & Shiv, 1998). Wanke, Bless, and Schwarz (1998) found that when the name of a sports car extension suggested continuation rather than discontinuation of prior models of the brand, people evaluated the new extension positively (as they would a typical sports car). Conversely, when the name suggested discontinuation, contrast effects occurred, particularly among nonexperts.

Research on alignable differences produces analogous effects as similarity and typicality. Alignable (versus nonalignable) differences have been found to increase brand evaluations in comparative ads (Zhang, Kardes, & Cronley, 2002).

A different research stream finds that the linear relationship between typicality and attitude breaks down in certain contexts, and shows that moderate levels of typicality induce more positive affect than low or high levels of typicality. According to this view, when consumers have abundant cognitive resources and are highly motivated to process information, the thought processes generated under a moderate level of incongruity are more pleasing than under a low level of incongruity. Meyers-Levy and Tybout (1989) argue, based on Mandler's (1982) moderate incongruity effect, that the process of resolving incongruity is pleasing, as long as people have the necessary resources and the incongruity is not too great. If the category is extremely similar, elaborative thought is less likely to be generated, resulting in more mildly positive affect. Meyers-Levy and Tybout found that the resulting positive affect deriving from the effort does indeed transfer to the target stimulus. Other research replicates the moderate incongruity effect (Meyers-Levy, Louie & Curren, 1994; Stayman, Alden & Smith, 1992). Peracchio and Tybout (1996), however, argue that for the moderate incongruity effect to occur, people need to have low prior knowledge of the category. Specifically, people with low prior knowledge will be more sensitive to category-inconsistent information, whereas people with high prior knowledge will be more likely to rely on their prior knowledge about salient category attributes. Peracchio and Tybout's findings support these predictions. Other research finds that the effect disappears under conditions of risk aversion (Campbell & Goodstein, 2001), or for people high in dogmatism (Meyers-Levy & Tybout, 1989).

Finally, under some circumstances, novelty and variety increase affect (Woll & Graesser, 1982). To the extent that a novel or unusual category member is more atypical of the category, typicality and affect are related negatively (Ward & Loken, 1988). In this case, the atypical members of the category are positively valued for their novel attributes. An area for future research is to investigate under what conditions these attributes are considered novel and positive, and under what conditions they appear atypical and less positive. In sum, however, most studies support a strong positive, linear relationship between typicality and affect, as long as the category has valued attributes. In more limited contexts, a nonlinear or even a negative relationship may exist.

METHODOLOGY AND ANALYTIC TECHNIQUES

In examining the extensive roles that category representation and category inference play in consumer information processing, researchers have had to draw on a diverse set of traditional methodologies, but have relied primarily on two. Many studies of category structure (e.g., category stability/flexibility and graded structure) have relied on correlational methods. As mentioned in an earlier section, various measures (ideals, attribute structure, fuzzy-set measures) are correlated with global measures of prototypicality (e.g., Barsalou, 1985, Loken & Ward, 1987, 1990; Ward

& Loken, 1986; Viswanathan & Childers, 1999). Similar correlational studies have been used in studying the roles that context and goals play in altering category representations (e.g., Barsalou 1982; Ratneshwar & Shocker 1991), and in altering the relationship between prototypicality and affect (Loken & Ward 1990; Ward & Loken 1988). One pertinent question is whether some of the measures discussed earlier (e.g., ideals, attribute structure, fuzzy set-based measures) can accommodate both taxonomic categories (which often have surface-level resemblances) and situational, goal-derived categories. The ideals measure captures the common goal(s) for both taxonomic and goal-derived categories (Barsalou, 1985; Loken & Ward, 1990). The attribute structure measure (Loken & Ward, 1990; Viswanathan & Childers, 1999) and fuzzy set measures (Viswanathan & Childers, 1999) capture the central tendency of categories, and feature elements can include both physical and nonphysical features of the category, as well as goals and/or image attributes. In the case of all three measures, the underlying attributes and goals are accessed via representations that are accessible for the category. Furthermore, because the attributes accessible in one context may differ from those accessible in another, the measures can accommodate and allow researchers to predict category fluctuations as a function of context.

The majority of the research in consumer categorization has relied not on correlational methods, but on experimental methods. When investigating category inferences in the context of brand categories and brand extensions, for example, researchers have typically presented consumers with information about a new category member (the extension) and then asked them to provide one of several conceptually relevant responses (e.g., choice, purchase intention, evaluation, beliefs, cognitive responses, see Aaker & Keller, 1990; Gurhan-Canli & Maheswaran, 1998; John, Loken, & Joiner, 1998; Lane, 2000; Loken & John, 1993; Meyvis & Janiszewski, 2004; Milberg, Park, & McCarthy, 1997). In these experiments, stimuli (extensions) and context information (brand category characteristics) are sampled or created such that the factors of interest that are being tested vary (e.g., presence of brand specific associations, Broniarczyk & Alba, 1994; brand breadth, Meyvis & Janiszewski, 2004; brand variability, Dacin & Smith, 1994; extension-category similarity Park, Milberg, & Lawson, 1991). Similar experimental methods have been used to examine the role of concepts in memory (e.g., Keller, Heckler, & Houston, 1998; Zhang & Markman, 1998) and inferences in induction (Levin & Levin, 2000; Park, Jun, & Shocker, 1996). Research on category expansion and flexibility has utilized measures of clustering and categorization/grouping as dependent variables (e.g., Isen & Daubman, 1984; Kahn & Isen, 1993; Lee & Sternthal, 1999), as has research on expertise and category structure (e.g., Cowley & Mitchell, 2003).

Finally, researchers who have focused on the question of category activation have used priming as a means of gaining insight into the relative accessibility of concepts for information processing. Morrin (1999), for example, used a priming and response time methodology to investigate what impact brand extensions had on the accessibility of parent brand associations (see also e.g., Pechmann & Knight, 2002; Grewal et al., 1997; Forehand & Deshpande, 2001).

An interesting question is whether a greater future focus on the modality-specific representation view of conceptual knowledge proposed by Barsalou (1999) will require a broadening of the methods used to examine concepts and categorization.

CONCLUSIONS

Consumer research that borrows from theories of categorization dates back to the mid-1980s. During the subsequent two decades, consumer researchers have identified applications beyond traditional product categories that include brand categories, goal-related categories, cultural categories, and service employee categories, among others. Research has found that the categories typically

examined in consumer psychology have both stability and flexibility of structure, and that they are used across diverse environmental contexts. Also, consumers often adopt categories on the basis of goal-based criteria, rather than on more traditional structural and taxonomic criteria, and these goal-derived categories, as well as categories based upon one's self-view, are quite malleable and membership depends on the consumer context.

Research that further examines the roles of the brain's modality-specific systems in higher cognition is needed. Barsalou's (1999) conceptualization of categories as residing in these systems could be a fruitful direction for future research. Future research could aim to increase our understanding of how modality-specific processing and simulation affect consumers' perceptions of new category members, their representations of categories, and their inferences about new and existing category members.

Research has also furthered our understanding of factors that influence category inferences, specifically, inferences from category beliefs and attitudes to new category instances. Much of the work on category inferences has been conducted in the context of brand categories. Early research on the global construct of similarity gave way to more thoughtful analyses of the various dimensions of similarity relevant to understanding inferences from brand categories to new category members (e.g., similarity to the brand product categories, similarity to the brand's beliefs or image), along with important moderating variables (e.g., accessibility, diagnosticity) that increase perceived similarity and category inferences. Most research has examined category inferences pertaining to new category members (brand extensions), with relatively little research being conducted on factors that impact inferences between existing category members. For example how might advertising of Healthy Choice soups affect inferences about Healthy Choice frozen dinners? Or, if one branded product (say, Healthy Choice soups) increases in quality over time, how will this affect inferences about the quality of other branded products (e.g., Healthy Choice frozen dinners)?

Consumer research on inferences has also found that information about new category members (e.g., brand extension failures) can impact category beliefs, as long as the information about category members is accessible and relevant to the original category beliefs. Future research could also examine whether existing category members that are accessible and perceived negatively impact perceptions of the category as a whole. Also, the conditions under which representations of current category members are stable or unstable (e.g., if retrieved consistently across settings vs. inconsistently) may also influence the ability of category representations to resist change.

Consumer research has also examined conditions under which a new category member (typically a brand extension) is likely to be accepted as a category member of a favorably viewed category. Research that examines category expansion finds that certain motivational (e.g., positive mood), ability (e.g., product expertise), and contextual (e.g., category diversity) factors increase acceptance of new category members.

The extensive research on the relation between similarity (typicality) and affect generally shows a positive linear relationship between the two. Exceptions to this positive relationship occur, however, and a greater understanding of these contingencies would be useful. In particular, how prevalent and important are these exceptions? What is the impact of these exceptions on marketing decisions?

In conclusion, in the past two decades, consumer research on category representation and category inferences has yielded important theoretical and managerial insights. Consumer researchers have found categorization concepts useful for a variety of types of consumer-driven categories and for a variety of marketing applications. Consumer categorization research has used insights from cognitive and social psychology to further understand consumer applications such as branding and goal-derived categories. These findings, in turn, increase our basic understanding of how cat-

egories are represented, the nature of retrieval of category representations, the functional location of category representations, the conditions under which category inferences are generated, and contextual factors that influence flexibility of category boundaries.

NOTE

1. More generally, researchers in cognitive science define a *category* as a set of entities, states, or events that appear coherently related in some way. In turn, they define a *category representation* as the integrated knowledge acquired from experiencing the category's members, and also from reasoning about them (Barsalou, 2003a, 2003b; Murphy, 2002; Smith & Medin, 1981). The term *concept* is often used interchangeably with the term *category representation*, with both referring to mechanisms in the cognitive system that represent and process categories.

Consumer Inference

FRANK R. KARDES

Miami University

PAUL M. HERR

University of Colorado

Consumers frequently make judgments and decisions based on limited or incomplete information. Secondhand sources of product information (e.g., information from advertising, promotion, or word-of-mouth communication) typically provide information about some product properties and characteristics (e.g., some attributes and benefits), but other properties and characteristics must be inferred by going beyond the information given (Bruner, 1957). To form inferences, consumers generate if-then linkages that associate information (e.g., cues, heuristics, arguments, knowledge) to conclusions in a subjectively logical fashion (Kardes, 1993; Kardes, Posavac, & Cronley, 2004; Kruglanski & Webster, 1996).

Subjective logic is based on perceptions of plausibility. People assess plausibility frequently and routinely, and plausibility judgments are so fundamental to reasoning that they are often formed without awareness or intention (Connell & Keane, 2004; Hirt, Kardes, & Markman, 2004). The primary determinant of plausibility is conceptual coherence, or the extent to which presented information matches or is consistent with prior knowledge stored in memory. That is, relationships between presented information and prior knowledge are explored, inferences implied by the presented information are formed, and the degree to which the implications of the presented information match the implications of prior knowledge determines the degree of plausibility of the presented information. Recent text comprehension research shows that different types of inferences influence plausibility to different extents: sentence pairs linked by causal inferences are rated highest, followed by missing attribute inferences, and lastly by temporal inferences (Connell & Keane, 2004). This chapter is organized in the following order: causal inferences are discussed first, followed by missing attribute inferences, and lastly by temporal inferences. Before discussing

different types of inferences, however, we review methodologies for assessing spontaneous inference formation.

SPONTANEOUS INFERENCE FORMATION

To study inferences, researchers must ask participants questions about their inferences. However, questions about inferences are likely to encourage participants to form inferences that might not have occurred to them otherwise, in the absence of direct questioning. Hence, an important distinction must be drawn between spontaneous inferences that are formed naturally, and measurement-induced inferences that are formed as a result of direct questioning. This distinction is crucial because spontaneous inferences are more likely to generalize from the laboratory to the field (Kardes et al., 2004), are more accessible from memory (Kardes, 1988; Stayman & Kardes, 1992), are held with greater confidence (Levin, Johnson, & Chapman, 1988), and are more likely to influence other judgments and behavior (Fazio, 1995).

Spontaneous inferences are formed “in accordance with or resulting from natural feeling, temperament, or disposition, or from a native internal proneness, readiness, or tendency, without compulsion, constraint, or premeditation” (*Webster’s New Universal Unabridged Dictionary*, 1983, p. 1756). Questions about inferences compel participants to form inferences that might not have been formed under more natural conditions. Consequently, nonspontaneous measurement-induced inferences are low in external validity because consumers who receive many questions about inferences in laboratory settings are less likely to receive the same questions in field settings. Fortunately, many procedures are available for distinguishing between spontaneous versus measurement-induced inferences—including response latency analysis, recognition confidence, cued recall, word stem completion, and relearning.

Response Latency Analysis

The speed with which participants can respond to questions about inferences (in milliseconds) provides useful information about the nature of the inferences (Fazio, 1990, 1995). If the inferences had been formed spontaneously prior to questioning, participants can simply retrieve these inferences from memory and respond relatively quickly. By contrast, if the inferences had not been formed prior to questioning, several time-consuming cognitive tasks must now be performed. First, participants must search memory for an appropriate response to the questions. If none exist, they must form new inferences that are relevant to the questions. This involves searching memory for inference-relevant information, integrating this information, and then, finally, responding to the questions. As a result, relatively slow response latencies are observed when spontaneous inferences had not been formed prior to questioning.

Kardes (1988b) manipulated the fear of invalidity (Kruglanski & Freund, 1983), or concern about committing an inferential error, to motivate consumers to draw conclusions about product benefits based on arguments embedded in an ad for a new compact disc player. In high fear of invalidity conditions, the header of the ad stated that compact disc players vary dramatically in quality and some are very good and some are very bad. This perceived variability manipulation was designed to encourage consumers to think carefully about the information presented in the ad. By contrast, in low fear of invalidity conditions, an uninformative header (i.e., Compact Disc Players) raising no concerns about inferential accuracy was presented. The text of the ad contained three sets of arguments implying three conclusions that were either presented in the ad (explicit conclusion conditions) or omitted (implicit conclusion conditions). It was hypothesized that omitting conclu-

sions would enhance advertising effectiveness when consumers were motivated to draw their own conclusions, but not when they were unmotivated to do so.

Participants were asked to judge the validity of each conclusion and response latencies were measured for each judgment (conclusion latencies). Participants were also asked to indicate their overall evaluations of the advertised brand. Finally, response latencies for overall evaluations were measured (evaluation latencies). The results showed that conclusion latencies were slower in the low fear of invalidity/implicit conclusion condition than in the remaining three conditions. This pattern was observed because participants failed to draw their own conclusions spontaneously, prior to questioning. Because the target conclusions were omitted from the ad, participants failed to think about these conclusions until they were asked to do so. In response to these questions, participants had to construct an answer by recalling information that was presented in the ad and by construing its judgmental implications (a time-consuming computational process; Lichtenstein & Srull, 1985). In the remaining three conditions, participants could retrieve either a previously-perceived (in explicit conclusion conditions) or a previously-inferred (in implicit conclusion conditions) conclusion from memory (a relatively fast retrieval process; Lichtenstein & Srull, 1985). Hence, spontaneous inferences were formed when the fear of invalidity was high and when conclusions were implied but not presented explicitly.

Less favorable evaluations were formed in the low fear of invalidity/implicit conclusion condition than in the remaining three conditions. When explicit conclusions are omitted and consumers are unlikely to draw conclusions spontaneously, consumers miss the main point of the message and the ad is ineffective. In contrast, evaluation latencies were faster in the high fear of invalidity/implicit conclusion condition than in the remaining three conditions. This suggests that strong, more accessible attitudes are formed when consumers draw their own conclusions, rather than simply reading conclusions provided by the advertiser. Self-generated inferences are more accessible from memory (Moore, Reardon, & Durso, 1986), are held with greater confidence (Levin et al., 1988), and are less likely to encourage counterargumentation (Kardes, 1993), relative to information that is simply read.

A follow-up study conducted by Stayman and Kardes (1992) showed that spontaneous inference generation was also more likely when the need for cognition, or the extent to which people enjoy performing effortful cognitive activities (Cacioppo, Petty, Feinstein, & Jarvis, 1996), is high (vs. low). Conclusion latencies were slower in the low need for cognition/implicit conclusion condition than in the remaining three conditions. Although individuals who were high in the need for cognition were more likely to generate inferences spontaneously, these individuals were likely to use these inferences as inputs for attitude formation only when they were low (vs. high) in self-monitoring (Snyder, 1974). Individuals low (vs. high) in self-monitoring were more likely to use self-generated inferences because such individuals are more sensitive to information stored in memory. Because the need for cognition and self-monitoring were uncorrelated, and because spontaneous inference generation does not guarantee that inferences will be used as inputs for other judgments, stronger more accessible brand attitudes were formed by individuals who were both high in the need for cognition (and therefore more likely to generate inferences) and low in self-monitoring (and therefore more likely to utilize inferences).

Recognition Confidence

Following a brief delay, consumers often experience difficulty discriminating between implicit and explicit conclusions. Consequently, consumers often believe that their self-generated and spontaneously-inferred conclusions were actually presented explicitly in an ad or in a product description.

This type of memory confusion results in intrusions in measures of recognition memory. Kardes (1988a) presented arguments about product features that implied conclusions about product benefits. The arguments had the form: "Brand A has feature X," "if X then Y," therefore, "A has Y." For example, the arguments "Stresstabs contain B vitamins," and "B vitamins give you energy" imply the conclusion that "Stresstabs give you energy."

Forty-four randomly presented product claims were presented to participants who were asked to judge the plausibility of each claim. Conclusions were included in the set of product claims for half of the participants (explicit conclusion conditions) and were excluded for the remaining half (implicit conclusion conditions). Half of the claims were syllogistically related and half were not. Half of the product claims pertained to familiar brands and half pertained to unfamiliar brands. After rating the plausibility of each claim, participants were asked to perform an unexpected recognition confidence task in which they were asked to indicate how confident they were that each of 16 test conclusions were presented explicitly earlier during the plausibility judgment task.

Intrusions or high recognition confidence for conclusions that were implied but not presented (implicit conclusions) were of particular interest because prior research on source monitoring has shown that people experience difficulty in discriminating between perceived versus inferred conclusions when inferences are formed with relatively little processing effort (Johnson & Raye, 1981). Recognition confidence was higher when the product claims were syllogistically related (vs. unrelated). Even though the arguments were presented randomly, participants inferred implicit conclusions even though they were not asked to do so, and later, participants experienced difficulty determining whether these conclusions were presented or inferred. This pattern was observed for familiar and unfamiliar brands. A different pattern emerged for explicit conclusions: recognition confidence was higher for familiar brands, regardless of whether the conclusions were logically related to the premises. The results imply that syllogistic inferences are formed spontaneously, and memory intrusions (i.e., high recognition confidence for information that was not presented) provide a useful measure of spontaneous inference formation.

CUED RECALL

Cued recall procedures are based on the encoding specificity principle which suggests that, "specific encoding operations performed on what is perceived determine what is stored, and what is stored determines what retrieval cues are effective in providing access to what is stored" (Tulving & Thomson, 1973, p. 369). Memory performance is enhanced to the extent to which contextual cues present during encoding or learning match the contextual cues present later during retrieval. If consumers form spontaneous inferences while learning about a product, the inferences will be encoded along with the presented information, and later, the inferences will serve as effective retrieval cues. Winter and Uleman (1984) applied this procedure to the study of spontaneous trait inference. Participants were asked to memorize 18 sentences, each of which implied a different personality trait. For example, the sentence, "The reporter steps on his girlfriend's feet during the foxtrot," implies the trait, "clumsy." After a 2-minute distraction task designed to clear short-term memory, participants received a memory test. During the memory test, some sentences were cued by the implied trait, some were cued by a semantic associate of the actor (e.g., newspaper), and some received no cue (free recall). The results showed that memory performance was better when implied traits or semantic associates were used as recall cues than when no cues were provided. This pattern suggests that implied traits were inferred spontaneously during encoding. This pattern has been replicated many times (for a review, see Uleman, Newman, & Moskowitz, 1996).

This procedure could be applied to the study of spontaneous inferences about products and services. Sentences describing the attributes, features, or characteristics of products could be presented during the learning phase of an experiment. The sentences should imply a key benefit. For example, the sentence, "Automobile X has a sturdy frame," implies the benefit, "longlasting." Subsequently, the implied benefit (longlasting) should be an effective recall cue. It is also possible that a product claim might imply several different inferences. For example, a sturdy frame might imply "safe" or "low gas mileage" in addition to "longlasting." Presumably, each of these cues, if they were inferred spontaneously, should improve memory performance, relative to a no-cue control condition.

Many variations of the cued recall procedure are possible. For example, in one variation, participants were asked to memorize strings of digits (Winter, Uleman, & Cunniff, 1985). Each string was followed by a "distractor sentence" to read aloud and repeat from memory. After a two-minute anagram distractor task, participants received an unexpected cued recall test for the trait-implicating "distractor sentences." Memory performance for the "distractor sentences" was greater for trait cues than for semantic cues, and greater for semantic cues than for no cues. This pattern suggests that spontaneous trait inferences were formed even though participants were not asked to memorize the "distractor sentences."

Word Stem Completion

Implicit memory measures can also be useful for distinguishing between spontaneous versus measurement-induced inferences. One such measure is word stem completion, in which participants read trait-implicating sentences with comprehension instructions and later fill in the missing blanks for implied traits (e.g., CL _ _ _ _ for the implied trait "clumsy"). A target trait word is more likely to be completed if it was implied by the sentences than if it was not implied, and word stems (i.e., supplying the first two letters of a word) are more sensitive measures of spontaneous inference formation, relative to word fragments (i.e., supplying random letters instead of the first two letters; Uleman et al., 1996; Whitney, Waring, & Zingmark, 1992). The word stem completion procedure can be used as readily for implied product benefits as for implied personality traits. Exposure to product claims implying benefits such as safety or healthy should lead to greater completion rates for word stems such as SA _ _ _ _ or HE _ _ _ _ , respectively.

Relearning

In a relearning paradigm, participants memorize information at Time 1, and then, at Time 2, memorize the same information again (old information) and new information. Memory performance is usually better for old information than for new information (Carlston & Skowronski, 1994; Uleman et al., 1996). For example, Carlston and Skowronski (1994) presented photographs of 29 people paired with self-descriptive trait-implicating sentences (e.g., "I hate animals and I kicked a puppy" implies the trait "cruel"). Participants were instructed to either familiarize themselves with the information or to form impressions of each person. At Time 2, some old photograph-sentence pairs were presented again and some new photograph-sentence pairs were presented. Trait recall was greater for old pairs than for new pairs, regardless of the experimental instructions. This pattern suggests that spontaneous trait inferences were formed in familiarization conditions. The relearning paradigm can be used as readily for studying spontaneous benefit inferences as for spontaneous trait inferences. After presenting attribute-benefit pairs and brand-benefit pairs at Time 1, memory performance should be better for old pairs than for new pairs at Time 2.

The Automatic-Deliberative Processing Continuum

Inferences can be formed automatically (i.e., without awareness) or deliberately (i.e., goal-directed inferences formed with awareness and intention). Automatic inferences are common in text comprehension. For example, when reading a passage stating that an actor pounded a nail into the wall, people automatically infer that the actor used a hammer (Bransford & Johnson, 1972). Less obvious inferences that require deliberation, however, are formed spontaneously only when consumers are sufficiently motivated (Kardes, 1988; Sawyer & Howard, 1991) and able (Maheswaran & Sternthal, 1990) to do so. The degree of motivation and ability required for spontaneous inference formation varies as a function of the strength of the evidence (e.g., a Rolls Royce is so luxurious that it is difficult not to infer that it is luxurious) and on consumers' goals (e.g., consumers interested in purchasing a luxury automobile are likely to evaluate all automobiles in terms of luxuriousness).

CAUSAL INFERENCES

A consumer walks into a shop and purchases a bottle of water. This is a rather common occurrence, of course, but why did the person exhibit this behavior? The first explanation that may come to mind is that the person was thirsty. But, what if the person's car had just overheated, or the person had a dog in their car that needed water? Drawing conclusions about why people do things or why events occur are the basis of causal inferences.

Everyday we observe and experience events that need explanation, and thus causal inferences. Like other inferences, causal inferences may be implicit or explicit. Seeing someone purchasing a package of cigarettes in a store leads us to infer that the person is a smoker. Such an inference may be almost automatic, and we may be unaware of such an inference. Causal analyses and inferences become explicit and intentional when unexpected, negative, or threatening events occur (Bohner, Bless, Schwarz, & Strack, 1988; Hastie, 1984; Wiener, 1980a, 1985) when a person feels a loss of control of a situation (Hastie, 1984; Pittman & Pittman, 1980), and when questions about cause-effect relationships in a given situation become salient (see Hastie, 1984; Silvera & Laufer, 2005, for a review).

At the heart of causal inference is attribution theory, a family of diverse ideas and theories which attempt to explain how and why people gather and process information in order to formulate causal explanations. The motivations underlying why people make causal attributions are to control their environment and predict the future, based on the assumption that understanding the cause of outcomes and events allows us to control and predict them (Heider, 1958; Jones & Davis, 1965; Kelley, 1967; Weiner, 1980a, 1985). Three foundational bodies of theoretical work, Jones and Davis's (1965) correspondent inference theory, Kelley's (1967, 1972a, 1972b, 1973) attribution contributions of the covariation model and causal schema theory, and Weiner's affect and control theories related to attribution (Weiner, 1979, 1980a, 1980b, 1982, 1985) have strongly influenced the area of causal inference.

Correspondent Inference Theory

Correspondent inference theory (Jones & Davis, 1965; Jones, 1990) concerns how people make inferences about another person's underlying dispositions by extrapolating from their observed behaviors. For example, observing a famous celebrity endorsing a product (e.g., Tiger Woods appearing in a Nike ad) leads us to infer that the celebrity likes and uses the product. Thus, the goal is to correspond behaviors to stable dispositions, with the assumption that knowing a person's internal dispositions allows us to ultimately predict their behavior.

Beyond simply looking at internal dispositional states in formulating causal explanations of other people's behaviors, people must also determine to what extent situational variables influence behaviors. This idea is reflected in the law of noncommon effects (Jones & Davis, 1965), which formalized the idea that when behavior occurs in the presence of strong situational factors, an observer should not assume the other's behavior is the result of just a natural, internal disposition (Gilbert & Malone, 1995). In other words, one should not discount the situation when attempting to explain another's behavior. Kelley (1967) later extended this idea to form the discounting principle (i.e., when one potential cause is discounted to the extent that other causes are possible), and Ross (1977) labeled the tendency to discount the situation as the Fundamental Attribution Error (see also Jones & Harris, 1967; Miller, Jones, & Hinkle, 1981).

The reality that many people do not adhere to the directives given in the law of noncommon effects, and often make the fundamental attribution error, is known as correspondence bias (Gilbert & Malone, 1995; Jones, 1979, 1986; Jones & Harris, 1967). In a classic study, Jones and Harris (1967) first investigated the phenomenon while doing work on correspondent and dispositional inferences. Participants were shown essays that reflected either a pro- or anti-position on Cuba's leader, Fidel Castro. Participants were told either that the essayist had been free to choose his written position or had been instructed by the debate coach to defend an assigned position. Participants then tried to infer the true attitudes of the essay writers. As expected, under the free choice condition, pro-Castro essay writers were seen as very pro-Castro and anti-Castro essay writers were seen as very anti-Castro. But surprisingly, in the assigned position condition, test participants still ascribed pro- or anti-Castro attitudes to the essayists in a similar manner, even though they knew the position was assigned.

More recently, correspondent inferences have been examined in the marketing context of product endorsers. This research suggests that correspondent inferences are positively associated with consumers' attitudes toward the advertisement, the product, the endorser, and to purchase intentions for the product (Cronley et al., 1999; Silvera, Grape, & Sørsum, 2004; Sørsum, Grape, & Silvera, 2003).

Kelley's Covariation Model

Kelley's (1967) attribution theory, called the covariation model, describes the types of information people should consider when trying to determine causality, and suggests that causes and effects should covary. Unlike correspondent inference theory, Kelley's theories encompass causal explanations based on situational factors, as well as on dispositional factors.

Causes come in two types: arising from a person and their behavior (i.e., dispositional), and arising from the situation (Heider, 1958). To determine which cause is the driver of the behavior, Kelley suggested that three types of information should be examined: consistency information (e.g., To what extent does a person's behavior toward an object generalize across situations?), distinctiveness information (e.g., To what extent does a person's behavior toward an object generalize across objects?), and consensus information (e.g., To what extent does the actor's behavior toward an object generalize across people?).

The covariation model describes how patterns observed among these three types of information have implications for judgment about the extent to which the actor's behavior is attributed to his or her personal traits and characteristics, as opposed to other factors, such as some situational variable. Consider this example: John criticizes a certain neighborhood grocery store as having terrible customer service. In attempting to figure why John is making this criticism, we should consider the following: (1) Does John repeatedly voice this complaint? (consistency information); (2) Does John

only criticize this store and not all stores? (distinctiveness information); and (3) Do other people have a similar criticism of this store? (consensus information). High levels of each factor should lead us to attribute John's complaint to the fact that, indeed, the store has terrible customer service. Other combinations of the information may also yield relevant causal inferences. For example, high distinctiveness, low consistency, and low consensus would suggest a situation-driven attribution, specifically, that John is simply temporary upset about an isolated service experience, whereas low distinctiveness, high consistency, and low consensus would lead us to conclude that John is simply a complainer who is never satisfied.

Kelley's Causal Schemata

When consumers are unable to observe covariation patterns over time, they may form attributions from causal schemata based on prior knowledge. Based on our life experiences, we develop abstract and generalized cause-effect relationships (e.g., new products are improvements over old products), upon which we can draw when causal information is ambiguous or when confirmatory information is relatively uninformative (e.g., consumers expect an advertiser to say that its new product is the best).

Causal schemata are thought to be important to causal inferences for several reasons. First, they provide a type of inferential heuristic that allows us to make inferences quickly and easily. Second, causal schemata provide us with cause-effect "rules" that can be applied in a wide range of situations and provide us with a means to infer causality when information is incomplete, ambiguous, contradictory, and uninformative.

Weiner's Contributions to Casual Inference

Drawing on previous work by Kelley (1967) and others, Weiner (1979, 1980a, 1980b, 1982, 1985) combined locus of cause (dispositional vs. situational), stability (stable vs. temporary with regard to future occurrences), and a new factor of control (controllable vs. uncontrollable) into a model of casual inference. The controllability factor relates to a person's ability to control an outcome. For example, Mary has a poor dining experience in a restaurant. Is the cause of that experience within her control, such as she was in a bad mood and was rude to the wait staff, or is the cause beyond her control, such as there was a fire in the kitchen? Weiner's model also incorporates emotional processes and subsequent outcomes associated with each of the model's factors. For example, when negative outcomes result from stable (vs. temporary) causes, anger over the outcome is more likely.

While most of this work was conducted in situational contexts of personal achievement and helping behaviors, it has been applied in the marketing domain to areas of service recovery and customer satisfaction (e.g., Folkes, 1984; Folkes, Koletsky, & Graham, 1987).

The Role of Attributional Processes in Consumer Behavior

Attribution theory has had a central role in explaining a variety of important consumer behavior phenomena, in part because consumers typically make spontaneous (i.e., unintentional and without awareness) causal attributions to help them integrate incoming information, and form correct judgments and make satisfying choices (Hassin, Bargh, & Uleman, 2001). More specifically, researchers have observed that the manner in which consumers draw causal inferences affects their reactions to persuasive attempts (e.g., advertising, personal selling), evaluation of and responsiveness to comparative advertisements, satisfaction with products and services, response to service

failure, perceptions of corporate cause sponsorship, and responsiveness to word-of-mouth (WOM) communication.

Friestad and Wright (1994) proposed a model of how individuals respond when they are the target of a persuasive attempt such as an advertisement. Persuasion knowledge, the knowledge of marketers' tactics and motivations, is accumulated with maturity as well as life experience. Although Friestad and Wright (1994) discuss a number of factors that influence the extent to which consumers will think systematically about a given advertisement, in general, a consumer who has developed high persuasion knowledge will be better able to resist marketers' influence in part because he or she will be able to make correct attributions for why marketers behave as they do (i.e., to facilitate sales; Campbell & Kirmani, 2000; see also, Campbell & Kirmani, in this volume).

Recent research has shown how attributional processes affect consumers' responses to comparative advertisements. Jain and Posavac (2004) empirically demonstrated that comparative ads vary in terms of whether the comparison is more positive ("The competing brand is good but ours is better") or negative ("The competing brand is bad but ours is good"). Generally, ads that feature more negative references to competition tend to provoke more counterarguing and less support arguments than positive comparative ads. Moreover, negative ads typically are less believable, and produce lower brand attitudes. All of these effects obtain because consumers attribute more nefarious motives to advertisers (e.g., that they are biased, manipulative, etc.) when they make negative versus positive comparisons.

Although advertising is a primary source of information for the consumer, the perspectives of family and friends may be weighted much more heavily because such individuals are typically perceived to be more much credible than are advertisers (Richins, 1983). However, as noted earlier, consumers often form causal inferences to help them understand the reasons underlying others' behavior. Laczniak, Decarlo, and Ramaswami (2001) investigated how causal attributions of the provider of negative WOM information affect consumers' brand evaluations. These authors exposed consumers to a negative WOM communication characterized by one of three combinations of Kelley's (1967) information dimensions: (1) high consensus, high distinctiveness, high consistency; (2) low consensus, low distinctiveness, high consistency; and (3) low consensus, high distinctiveness, low consistency. As predicted, consumers exposed to negative WOM configured as high consensus, high distinctiveness, and high consistency were more likely to form negative brand inferences than consumers exposed to either of the other configurations. In contrast, consumers exposed to negative WOM configured as low consensus, low distinctiveness, and high consistency were more likely to infer that the negativity of the message was due to the communicator than consumers exposed to either of the other configurations.

While these effects are quite consistent with core attribution theory predictions, Laczniak et al. (2001) also explored the potential of brand strength to attenuate these effects. Specifically, when consumers are exposed to negative WOM about a strong brand, they are less likely to attribute message negativity to the brand than if the brand is weak because the negative information is discounted (Sanbonmatsu, Kardes, & Gibson, 1989) in light of prior favorable brand perceptions (cf. Herr, Kardes, & Kim, 1991). Moreover, brand strength relates to inferences regarding the communicator; message negativity is more likely to be attributed to the communicator to the extent that a brand is strong. Both brand and communicator attributions, in turn, have implications for brand attitudes. Specifically, when strong brand attributions are made, brand evaluations are more negative. In contrast, when message negativity is attributed to the communicator, brand attitudes are more positive.

Another influence on consumers' brand preferences is their evaluation of the firm that manufactures the brand. Accordingly, firms have been expending increasing resources on sponsorships

of events and social causes in an attempt to create more positive firm-level attitudes (Crimmins & Horn, 1996). Recent research has shown that consumers' attributions of the reasons underlying firms' sponsorship spending influence the extent to which firms will be successful in this endeavor. Rifon, Choi, Trimble, and Li (2004) demonstrated that the congruence, or goodness of fit, between a firm and the sponsored cause is a strong determinant of whether consumers will attribute the firms' sponsorship to either altruism or self-interest. To the extent that there is a good fit, consumers perceive the firm to have an altruistic motive, perceive the firm to be credible, and have favorable attitudes toward the firm. Moreover, these authors found that attributions were more favorable when a firm versus brand acted as a sponsor because the selling proposition is less obvious when a sponsorship occurs at the firm level.

A number of researchers have investigated how consumers' attributions of the reasons underlying service failures affect their perceptions and future behavior (Churchill & Surprenant, 1982; Folkes, Koletsky, & Graham, 1987). Folkes et al. (1987) for example, conducted a field study in an airport in which consumers who were booked on flights that were delayed were interviewed. Folkes et al. (1987) measured the extent to which consumers perceived that their flight was delayed due to factors controllable by the airline, and whether the cause of the delay was stable versus unstable. These attributional perceptions were strongly related to consumers' responses to the airline. To the extent that consumers inferred controllable and stable causes of the delay, they were angrier, and much less likely to repurchase tickets from the airline in the future. Controllability also affected consumers' propensity to complain; consumers who drew inferences that the delay was controllable were more likely to complain.

Recent research has focused more generally on the role of attributions in satisfaction. Weiner (2000) discussed the role of stability attributions in determining product satisfaction. When consumers experience a product outcome, they often engage in attributional thinking to inform their subsequent decision making. The intuitive attribution analysis is particularly likely when an experience is negative. To the extent that an outcome is stable versus unstable, consumers perceive that their experience will be predictive of future product satisfaction, and have an associated affective response (e.g., anger or fear in the event of a negative outcome). This expectation, then, guides future behavior (e.g., Will the consumer repurchase? What will the consumer tell friends about the product?).

Weiner (2000) also delineated how perceptions of responsibility (i.e., is the consumer or the company/brand responsible for the product experience), affect consumer behavior when a negative outcome is experienced. If the attributional search that follows a negative experience results in the inference that the company is responsible for the outcome, anger will typically result, and consumer responses such as failure to repurchase, complaining, and attempts to punish the company are likely. An internal attribution is unlikely to provoke such affective and behavioral responses.

Tsiros, Mittal, and Ross (2004) provided a more fine-grained analysis of the complex interactions attributional processes have in determining satisfaction. These authors explored the roles of responsibility and stability attributions when an expectation is disconfirmed. When a disconfirmation occurs and is perceived to be unstable, whether the company is judged to be responsible for the disconfirmation has no moderating role in satisfaction. However, when the disconfirmation is attributed to be stable, company responsibility plays a crucial role in determining satisfaction; to the extent that the company is responsible for a stable disconfirmation, positive disconfirmations result in particularly high satisfaction, whereas negative disconfirmations produce strong dissatisfaction.

MISSING ATTRIBUTE INFERENCES

Consumers often use implicit theories—or prior beliefs about the relationships among people, objects, and events—to link arguments and evidence to conclusions (Wyer, 2004). Many different implicit theories are possible—such as implicit theories about interattribute correlations, categories, accessibility experiences, and perceptual fluency. In each of these cases, implicit theories are used to reduce ambiguity by filling gaps in knowledge and by helping consumers to make predictions. Implicit theories can contain a single, simple if-then linkage (e.g., if a product is expensive, it must be good; Kardes, Cronley, Kellaris, & Posavac, 2004) or multiple sets of if-then linkages, such as those found in syllogisms or sets of syllogisms (e.g., Kardes, Cronley, Pontes, & Houghton, 2001).

If-then linkages can be idiosyncratic (e.g., if it is a Lynch Bages, it must be a good wine) or shared widely (e.g., if it is expensive, it must be good), and once consumers learn an if-then linkage, confusion of the inverse is likely. That is, if consumers believe one concept implies another (if X, then Y), they also believe that the second concept implies the first (if Y, then X; Wyer & Srull, 1989). Consequently, for implicit theories about interattribute correlations, if a product is expensive it is good (if X, then Y) implies that if a product is good it is expensive (if Y, then X). For implicit theories about categories, if a product is Japanese it is good (if X, then Y) implies that if a product is good it is Japanese (if Y, then X). For implicit theories about accessibility experiences, if a product is good it is easy to think of reasons for liking it (if X, then Y) implies that if it is easy to think of reasons for liking a product it is good (if Y, then X). For implicit theories about perceptual fluency, if a product claim is true it is familiar (if X, then Y) implies that if a product claim is familiar it is true (if Y, then X). Similarly, important ideas draw attention (if X, then Y) implies that attention-drawing ideas are important (Wyer & Srull, 1989). Confusion of the inverse is quite common in subjective logic and in inferential (if-then) reasoning.

Implicit Theories About Interattribute Correlations

The most widely studied inferences in consumer research are correlation-based inferences (for a review, see Kardes et al., 2004). Consumers often hold implicit theories that product quality is positively and strongly correlated with price, warranty, packaging, fit and finish, and other cues. To the extent that two variables are correlated, information about one variable enables consumers to draw inferences about the other. Many studies have shown that implicit theories or expectations about interattribute correlations dominate data-based judgments about interattribute correlations (e.g., Broniarczyk & Alba, 1994b, 1994c; Cronley, Posavac, Meyer, Kardes, & Kellaris, 2005; Kardes, Cronley, Kellaris, & Posavac, 2004).

Broniarczyk and Alba (1994c) presented price, quality, and advertising expenditure information for 25 brands of stereo speakers during the data-based learning phase of an experiment. Next, during the judgment phase, participants either judged the strength of the correlation between price and quality and between advertising and quality, or they predicted quality based on price or advertising. Correlation judgments were more accurate than predictive judgments even though, normatively, prediction is based on correlation. Moreover, participants overestimated the strength of the price-quality relationship and underestimated the strength of the advertising-quality relationship except when price and quality were uncorrelated or advertising and quality were perfectly correlated during the learning phase. This pattern of results suggests that consumers overestimate the strength of the relationship between two variables when the two variables are linked by an implicit theory (i.e., price and quality) and that consumers underestimate the strength of the relationship

between two variables when the two variables are not linked by an implicit theory (i.e., advertising and quality), except when the data are very strong (i.e., correlations of zero or one).

Surprisingly, Broniarczyk and Alba (1994c) found no effects of information presentation format (i.e., rank ordered by quality vs. random) on judgment. Kardes et al. (2004) reasoned that format effects would emerge if cognitive load were sufficiently high and the motivation to search for information inconsistent with one's implicit theory were sufficiently low. To test this hypothesis, load was manipulated (i.e., price-quality data for 10 brands vs. 100 brands of wine) and the motivation to search for disconfirming evidence was manipulated by varying the need for cognitive closure—or the desire for a definite answer to a question or problem, any answer, as opposed to confusion and ambiguity (Kruglanski & Webster, 1996). Information presentation format (price-quality data rank ordered by quality or presented in a random order) should affect the ability to process information (rank ordered data are easier to process) as well as sensitivity to disconfirming evidence (randomly presented data increase sensitivity to disconfirming cases). These dual processes should produce opposite effects: a random format should reduce the ability to process information carefully and this should reduce judgmental accuracy. However, a random format should also increase the likelihood that consumers will encounter disconfirming cases by chance and this should enhance judgmental accuracy.

The results showed that format had a greater informational effect than an ability-to-process effect on judgment. Although a random format is more difficult to process, this format enhanced judgmental accuracy because it increased sensitivity to information that disconfirmed consumers' implicit theories about the price-quality relationship. This result is important because it suggests that consumer researchers should allocate greater attention to informational variables. The vast majority of studies of consumer inference and persuasion have focused on variables that influence the motivation and the ability to process information carefully at the expense of informational variables or environmental variables that influence consumers' learning structures (Hogarth, 2001; Kardes, 2006).

The results of four experiments using different manipulations of the need for cognitive closure and different product categories (digital cameras, interior house paints, boxed chocolates) show that the degree to which consumers use price as a basis for inferring quality is reduced when the need for cognitive closure is low, provided that they encounter a large amount of information presented randomly. The results support a selective information processing explanation of correlation-based inference: Consumers focus selectively on information that confirms their implicit theories, except when the need for cognitive closure is low, load is high, and the format is random.

More direct evidence for the critical role of implicit theories in correlation-based inference was provided by Cronley et al. (2005). Implicit theories about the price-quality relationship were measured by asking participants to indicate their assumptions about the strength of the relationship on a scale ranging from 0 (no relationship at all) to 10 (extremely strong relationship). This scale was administered before and after the learning phase of Experiment 4. The results showed that the learning phase changed participants' implicit theories in random format conditions, but not in rank ordered format conditions. Moreover, explicit instructions to focus on the presented information had no effects. The results suggest that a random format spontaneously increases learning, even though participants also indicated that learning is more difficult under these conditions.

Cronley et al. (2005) also ran mediational analyses on several experiments showing that sensitivity to disconfirming evidence mediates the effects of format, load, and the need for cognitive closure on price-quality inference. In their final experiment (Experiment 5), they showed that price-quality inference determines choice: When the need for cognitive closure was low, partici-

pants relied more heavily on price to infer quality and purchased more expensive wines when information was presented in a rank ordered format as opposed to a random format.

Of course, price is not the only cue used to infer quality. Consumers often assume that perceived advertising costs (Kirmani, 1990) and warranties (Boulding & Kirmani, 1993) are also correlated with quality. The accessibility-diagnostics model (Feldman & Lynch, 1988; Lynch, Marmorstein, & Weigold, 1988) suggests that many different types of information can be used as inputs for judgment, and the inputs that are most accessible from memory and that are the most relevant or diagnostic are the inputs that are weighed the most heavily in judgment. Accessibility increases as salience, vividness, or elaborative processing increases, and diagnosticity increases as the perceived correlation between two variables increases. Research on warranty-quality inference shows that manufacturer reputation and retailer reputation influence the extent to which consumers use warranty information to infer quality (Purohit & Srivastava, 2001). Participants were given information pertaining to manufacturer reputation and retailer reputation and warranty coverage (4 months vs. 24 months) and were asked to evaluate a new computer (Purohit & Srivastava, 2001). When manufacturer or retailer reputation was favorable, warranty information was used to infer product quality, and better warranty coverage led to higher perceptions of quality. When manufacturer or retailer reputation was unfavorable, however, warranty information had no effect.

Dick, Chakravarti, and Biehal (1990) showed that accessibility-diagnostics theory can be applied to other variables as well. When an accessible attribute is diagnostic because it is assumed to be correlated with a missing attribute, correlation-based inferences are formed. When diagnosticity is low because none of the accessible attributes are assumed to be correlated with a missing attribute, attitude-based inferences are formed (i.e., favorable [unfavorable] overall evaluations imply favorable [unfavorable] missing attributes). When correlations are low and attitudes are inaccessible or nondiagnostic, judgments are adjusted toward a more moderate position (Kardes & Sanbonmatsu, 1993).

Discounting and Slope Effects. Many studies of judgment based on missing information compare evaluations of products described on two attributes, A and B (e.g., price and quality), with evaluations of products described on one attribute, A or B. Products are evaluated less favorably when information about one attribute is missing than when this attribute is described as average for the product category (Huber & McCann, 1982; Jaccard & Wood, 1988; Johnson, 1987, 1989; Johnson & Levin, 1985; Lim, Olshavsky, & Kim, 1988; Meyer, 1981; Slovic & MacPhillamy, 1974; Yamagishi & Hill, 1981, 1983). At least three processes can lead to negative adjustment or discounting: (1) consumers may form correlation-based inferences with a negative adjustment (the correlation-based inference hypothesis), (2) consumers may treat missing information as a negative cue and this cue may be integrated separately with the evaluative implications of the presented information (the negative cue hypothesis), or (3) overall evaluations may be adjusted toward a more moderate position to correct for uncertainty caused by the detection of missing information (the inferential correction hypothesis of omission neglect theory).

In addition to discounting, many studies have observed a slope effect: In two-attribute contexts, the marginal effect of manipulations of the favorableness of the presented attribute on overall evaluations (i.e., the slope) is weaker when information about the other attribute is omitted as opposed to presented. Johnson and Levin's (1985) model of correlation-based inference captures the discounting effect and the slope effect. When attribute A is presented and attribute B is missing:

$$R = w_A s_A + w_B s'_B, \quad (1)$$

where R is the overall evaluation, s_A is the evaluation of A, s'_B is the inferred value of B, and the w 's are weights that sum to one. The inferred value of B is:

$$s'_B = ms_A + k, \quad (2)$$

where m is the subjective correlation between A and B, and k is a constant that is often negative to reflect a penalty for missing information. When $m=0$ and k is negative, discounting is predicted. When m is negative and $k=0$, a slope reduction is predicted. When m is positive and $k=0$, a slope increase is predicted, but this effect has been observed in only a few studies (Johnson, 1989; Lim et al., 1988). Simmons and Lynch (1991) found discounting and slope effects without any evidence of correlation-based inference. Of course, correlation-based inference is just one type of inference process and other types are possible.

When people suspect that an initial judgment is invalid, they attempt to adjust this judgment to correct for perceived sources of bias using implicit theories about bias to guide the direction and the magnitude of the inferential correction (Gilbert, 2002; Johar & Simmons, 2000; Petty & Wegener, 1993; Wegener & Petty, 1995; Wilson, Centerbar, & Brekke, 2002). Judgment adjustment requires cognitive effort, and consequently, as cognitive load increases (due to time pressure, set size, simultaneous tasks, etc.), the amount of adjustment decreases. Hence, cognitive load manipulations provide a useful tool for separating initial and final judgments and for determining the direction and the amount of adjustment that is performed.

Omission Neglect. Consumers often use whatever information is readily available to them and neglect missing, unmentioned, or unknown information (Kardes & Sanbonmatsu, 2003). As a consequence, consumers often form extreme and confidently-held judgments on the basis of weak or limited evidence. Sensitivity to omissions increases and more moderate judgments are formed, however, when consumers are warned that information is missing (Sanbonmatsu, Kardes, & Herr, 1992), when consumers are highly knowledgeable about a product category and have well-articulated standards of comparison (Sanbonmatsu, Kardes, & Sansone, 1991; Sanbonmatsu et al., 1992), and when comparison processes make it painfully obvious that different products are described by different amounts of information (Muthukrishnan & Ramaswami, 1999; Kardes & Sanbonmatsu, 1993; Sanbonmatsu, Kardes, Houghton, Ho, & Posavac, 2003; Sanbonmatsu, Kardes, Posavac, & Houghton, 1997).

Although omissions are typically not salient, variables that increase the salience of omissions help consumers to recognize that their judgments are based on weak or limited evidence, and this encourages inferential correction toward a more moderate position. When information is weak or limited, moderate (vs. extreme) judgments are more accurate (Griffin & Tversky, 1992), more readily updated as new information becomes available (Cialdini, Levy, Herman, & Evenbeck, 1973), and are more justifiable to oneself and others (Lerner & Tetlock, 1999; Shafir, Simonson, & Tversky, 1993).

Contextual cues that prompt the recognition of specific omissions are more likely to be present in comparative (vs. singular) judgment contexts, and, consequently, set-size effects are more likely to be observed in comparative within-subject than in singular between-subject designs. However, even in within-subject designs, sensitivity to missing information is greater when the product described by the larger amount of information is presented second as opposed to first (Kardes & Sanbonmatsu, 1993) and when products are described on noncomparable attributes (Sanbonmatsu et al., 1997).

Comparative judgment contexts also reduce the tendency to overestimate the importance of the presented information (Sanbonmatsu et al., 2003). Half of the participants judged an automobile described by limited information (three noncomparable favorable attributes) singularly, and half judged this product in the context of another automobile described by a larger amount of information (six noncomparable favorable attributes). An open-ended measure of attribute importance

was employed. Participants were asked to list at least four and not more than eight attributes that are important to consider in evaluating an automobile, and to explain why each listed attribute is important. One of three different sets of attributes was used to describe the target product, and for whichever set was used, the attributes describing (vs. not describing) the target product were more likely to be reported as important in the singular judgment context, but not in the comparative judgment context. Moreover, as the perceived importance of the information used to describe the target product increased, the perceived sufficiency of this information increased, and evaluation extremity increased.

Sensitivity to missing information is an important precursor to inference formation: Consumers are unlikely to infer values for missing attributes unless missing attributes are detected. Moreover, employing procedures that increase sensitivity to missing attributes—such as comparative judgment contexts, a priori criteria consideration and a priori rating of all relevant attributes (regardless of availability)—improve judgment by debiasing omission neglect (Kardes & Sanbonmatsu, 2003; Kardes et al., 2006).

Implicit Theories About Categories

Implicit theories about interattribute correlations are not the only basis for inference formation. Consumers also use implicit theories about categories to draw inferences about products. Categorical information includes product types (e.g., cars) and subtypes (e.g., sports cars), prototypes (e.g., abstract representations of the typical member of a category) and exemplars (e.g., concrete representations of specific members of a category), country of origin (e.g., all products made in Japan are high in quality) and brands (e.g., all products made by Sony are high in quality). In each of these examples, categorical reasoning involves generalization: A specific product is assumed to possess properties similar to those possessed by a category (e.g., product type, subtype, prototype, exemplars, country of origin, brand) to which the product is linked. Again, if-reasoning is involved (if it is a Sony, it is high in quality) and confusion of the inverse is common: If a product has features in common with a particular category, then it is a member of that category (if X, then Y); if a product is a member of a category, then it has features in common with that category (if Y, then X).

There are two major models of category-based inference: the Fiske and Pavelchak (1986) feature-matching model and the Brewer (1988) involvement model. Fiske and Pavelchak (1986) suggest that the features of a target object are compared to the features of a category, and if sufficient match or overlap exists, the object is assigned to the category and features typical of the category are assumed to be shared by the target object. If insufficient match or overlap exists, effortful piecemeal or attribute-based judgment occurs (e.g., Lynch, 1985). According to Brewer (1988), feature-matching is not as important or primary as involvement. When involvement is low, consumers attempt to assign a product to a category and category-based inference is likely. When involvement is high, effortful piecemeal or attribute-based judgment is likely.

Sujan (1985) conducted a study to delineate when individuals would engage in category versus piecemeal processing in a consumer context. She found that expert consumers, that is, those with well developed category knowledge, engaged in category-based processing when a target brand fits well with their knowledge of the relevant category. Specifically, they tended to arrive at evaluations of the brand quickly, and to consider more category information and less information specific to the singular brand. In contrast, when attributes of a brand did not match the category, expert consumers engaged in more analytical (i.e., piecemeal) processing of brand information that required more time than category-based processing, and arrived at final judgments of the brand that were based primarily on attributes of the brand versus the category.

This pattern did not hold for novice consumers, who have much less well developed category knowledge. While novices in Sujan's (1985) study were able to recognize when target brands matched versus did not match a given category, they typically made category-based inferences whether the target match matched the category or not. Rather than the normatively appropriate piecemeal processing strategy when a brand does not match its purported category, novices may be overly likely to use general feelings about a given category in evaluating a new brand claimed to belong to the category.

Sujan and Dekleva (1987) compared three ad types: (1) a noncomparative ad that introduced a new brand as belonging to a given product category (i.e., camera), (2) a noncomparative ad that introduced the new brand as belonging to a given subcategory (i.e., 35 mm SLR camera), and (3) an ad in which the new brand was compared to a well known competitor within the given product type. For both experts and novices, comparative ads that positioned a new product as belonging to a given product category, resulted in greater perceived ad informativeness, greater perceived similarity between the advertised brand and competitors, and greater perceived differences versus brands belonging to another category. For experts, but not novices, comparative ads were superior on these measures, relative to noncomparative ads that positioned a new product as belonging to a given product type. Ad-induced inferences were shown to mediate all of these effects.

Country-of-Origin Categories. Hong and Wyer (1989) asked participants to form an impression of a product or to judge the comprehensibility of the given information. Although country of origin (e.g., Japan or Mexico) typically had a direct influence on product evaluations, in the comprehension conditions it had the additional role of priming participants' interest in the product and increasing the care with which they processed attribute information. Attribute information, in turn, had a greater influence on product evaluations. In contrast, participants in the impression formation conditions always processed attribute information carefully.

Hong and Wyer (1990) replicated Hong and Wyer (1989) and demonstrated the importance of the timing of information presentation. Participants received country of origin information either before or after brand attribute information was presented, and these two sources of information were either presented sequentially or after a 24 hour delay. After receiving both sources of information participants completed brand evaluations, were asked to recall the information they received, and evaluate the favorableness of each brand attribute. Category-based (country-of-origin based) inference occurred in many experimental conditions, but different processes occurred depending on the timing of information presentation. When attributes were presented before country of origin, or country of origin was revealed immediately before attribute information, country of origin served as an ordinary attribute, and its evaluative implications were aggregated along with the evaluative implications of the other attributes. When country of origin was presented 24 hours before attribute information, however, country became a distinct concept that guided subsequent processing. Specifically, participants' perceptions of the country of origin directly affected overall evaluations, but additionally affected estimations of the favorableness of brand attributes such that ambiguous attributes were rated more favorably when the country of origin was reputed to make high versus low quality products.

Country of origin also affected the favorableness of unambiguously positive or negative attributes when there was a delay between the country of origin information and attribute ratings. Specifically, assimilation effects were evident such that when the country was reputed to make positive products, positive attributes were perceived more favorably, and when the country was reputed to make poor products, negative attributes were perceived less favorably. Contrast effects were also present. Specifically, when there was a mismatch between the reputation of the country and attribute valence (favorable country reputation paired with a negative attribute or an unfavorable country reputation paired with a positive attribute), the attribute was perceived more extremely in its

initial direction. In cases of both match and mismatch between the reputation of the manufacturing country and attribute valence, learning the country in which a product was made led to more extreme perceptions of the unambiguous attributes.

Li and Wyer (1994) provided further insight into how a product's country of origin affects consumers' evaluations of it. In this study, country was particularly likely to serve as an independent attribute when context facilitated consumers' consideration of all available product information, specifically, when decision importance was high and when country of origin information was conveyed prior to other attribute information. Country of origin also was used in inference formation regarding missing attributes of a familiar product type (a wristwatch) when little product information was available. Finally, country of origin was shown to serve as a standard of comparison for product evaluations. When a consumer is familiar with a product described by a large amount of information, or is making an unimportant decision in which country information is encountered after attribute information is processed, contrast effects may emerge in which the product is perceived less favorably because of the lofty expectations regarding products made in that country.

Brand Categories. Extensive research has shown that when an unfamiliar new product is linked to a familiar brand category via brand extension (i.e., a shared brand name), the new product is assumed to have properties typical of the more general brand category (e.g., Aaker & Keller, 1990; Boush & Loken, 1991; Bridges, Keller, & Sood, 2000; Broniarczyk & Alba, 1994a; Chakravarti, MacInnis, & Nakamoto, 1990; Farquhar, Herr, & Fazio, 1990; Herr, Farquhar, & Fazio, 1996; Keller, 1993; Keller & Aaker, 1992; Park, Milberg, & Lawson, 1991). As implied by the Fiske and Pavelchak (1986) feature-matching model, the greater the match between a specific product and a more general brand category, the more likely it is that the product will be perceived as a member of that category. Consequently, properties typical of the brand category will be ascribed to the product. Several different matching procedures (e.g., similarity, fit, typicality, relatedness) have been investigated and when the match is high, brand category-based inference is likely. When the match is low, piecemeal or attribute-based judgment is likely.

Bridges et al. (2000) found evaluations of brand extensions were less favorable when the parent brand's dominant associations (i.e., those that define the brand within the marketplace along some positioning dimension; e.g., Volvo as "safe") were inconsistent with those of the extension brand. In this case, consistency was defined in terms of attribute-based vs. non-attribute-based dominant associations. Similarly, Park et al., (1991) found that product feature similarity determined extension evaluations but also found that product-level associations alone do not drive extension evaluations. The authors showed that consistency between parent and extension brands with respect to their brand-name-concepts (i.e., brand unique abstract meanings that are inferred from concrete brand features and are global in nature; e.g., Rolls Royce as "high social status") also influenced extension evaluations, with higher consistency resulting in more favorable evaluations of the extension. Herr et al. (1996) found that consumers' brand affect for category-dominant (e.g., Nike evokes the category of athletic shoes) brands transferred better to a proposed brand extension when the parent category and extension (target) category were closely (vs. distantly) related. Finally, Broniarczyk and Alba (1994a) argued that too much research attention has been allocated to similarity and too little to brand-specific associations. They found that salient brand-specific associations dominated brand affect and product category similarity in product evaluation.

Implicit Theories About Accessibility Experiences

Consumers have many implicit theories about how their minds work (metacognition) and about the implications of accessibility experiences—or experiences concerning the ease or difficulty with which information can be retrieved from memory or generated (Schwarz, 2004a, 2004b; Schwarz

& Vaughn, 2002). Many theories of consumer judgment (e.g., attribute-based judgment models, Lynch 1985; the accessibility-diagnostics model, Feldman & Lynch, 1988; Lynch et al., 1988) focus on accessible content, or the specific pieces of information that come to mind. Schwarz (2004a, 2004b; Schwarz & Vaughn, 2002) argues that accessibility experiences, or the subjective ease or difficulty with which that content comes to mind, are equally important or even more important, in some situations.

For example, in a classic study, people were asked to recall either 6 or 12 examples of their own assertive or unassertive behavior (Schwarz, Bless, Strack, Klumpp, Rittenauer-Schatka, & Simons, 1991). Participants rated themselves as more assertive when they recalled few (6) rather than many (12) examples of assertive behavior. They also rated themselves as more unassertive when they recalled few (6) rather than many (12) examples of unassertive behavior. It is easier to recall few rather than many examples of a particular type of behavior, and consequently, more extreme trait inferences are formed when few rather than many examples are recalled. Similar results have been found for brand evaluations: Recalling 1 reason to drive a BMW is easier and results in more favorable brand evaluations than recalling 10 reasons (Wanke, Bohner, & Jurkowsch, 1997). Ease of retrieval is informative in its own right, and ease dominates content when accessibility experiences are perceived to be diagnostic.

Different judgment tasks highlight different implicit theories about the implications of accessibility experiences. When it is easy to recall examples of a target event, people infer (a) that there are many examples when asked about frequency, (b) that the event happened recently when asked about timing, (c) that their memory is good when asked about memory clarity, (d) that the event is interesting or important when asked about interest or importance, (e) that the level of background noise is low when asked about distraction, and so on (Schwarz, 2004a). Schwarz (2004b) also found high levels of consensus for many different implicit theories about accessibility experiences, including “the more examples exist, the easier it is to bring some to mind; details of recent events are easier to recall than details of distant events; examples from categories that are well represented in memory are easier to recall than examples from categories that are poorly represented in memory; the more I know about something the easier it is to come up with examples; and things that are important to me are better represented in memory than things that are unimportant” (p. 370).

Schwarz (2004a) has shown that, over time, people might use different implicit theories, including implicit theories with opposite implications. For example, when asked to judge the quality of works of art, participants rated the work of art that took a long to complete (e.g., a year) as higher in quality than the work of art that took a short time to complete (e.g., a week). However, when asked to judge the talent of the artist, the artist that produced the work of art in a short period of time was rated as more talented than the artist that produced the work of art in a long period of time. Hence, the less talented artist produced the higher quality work of art.

Just as feelings of effort expenditure influence inferences about quality, so too do feelings of knowledge and ability. Consumers assume that if they spend a lot of time and effort thinking about an issue, they are likely to draw accurate conclusions. Similarly, if they have a lot of knowledge and experience regarding an issue, they assume that they are likely to draw accurate conclusions. However, the validity of consumers’ inferences and conclusions depends not only on motivation, effort, knowledge, and ability, but also on the learning structure afforded by the environment (Hogarth, 2001). Wicked environments provide minimal, noisy, or delayed feedback, whereas kind environments provide ample and immediate feedback with a high signal-to-noise ratio. Although inferential validity increases with the friendliness of the learning environment, consumers believe that they learn a lot as motivation (Mantel & Kardes, 1999) or experience (Muthukrishnan & Kardes, 2001) increases, regardless of the friendliness of the learning environment. Consequently, con-

fidently-held but invalid inferences are formed frequently in unfriendly learning environments (Kardes, 2006).

Several important moderators of the judgmental effects of accessibility experiences have been identified. People are more likely to use accessibility experiences when involvement or processing motivation is low, and are more likely to use accessible content when involvement or processing motivation is high (Schwarz, 2004a). Accessibility (accessibility-as-information; Schwarz, 2004a) and mood (mood-as-information; Schwarz, 2002) are both more likely to be used as heuristic cues when involvement is low. Both types of heuristic cues are also likely to be discounted when extraneous sources of feelings of accessibility or mood are salient. Accessibility experiences are also more likely to be used as inputs for judgment when accessibility is moderate rather than extremely low or high (Tybout, Sternthal, Malaviya, Bakamitsos, & Park, 2005). The use of accessibility experiences is also moderated by the need for cognitive closure (Hirt et al., 2004; Silvera, Kardes, Harvey, Cronley, & Houghton, 2005). For an unfamiliar judgment task involving the use of fault trees to diagnose reasons for system failure, accessibility experiences were used by high but not low need for cognitive closure individuals (Silvera et al., 2005). For a familiar judgment task involving generating reasons for predicting that a favored team will lose a key sporting event, accessibility experiences were used by low but not high need for closure individuals (Hirt et al., 2004).

Implicit Theories About Perceptual Fluency

Accessibility experiences pertain to memory-based judgments and the ease or difficulty with which information can be retrieved or generated. Perceptual fluency pertains to stimulus-based judgments and the ease or difficulty with which information can be perceived (Schwarz, 2004a). High figure-ground contrast, stimulus clarity, duration of presentation, and prior exposure (i.e., priming) increase perceptual fluency, and different theories about perceptual fluency have different implications for judgments of background noise, fame, familiarity, confidence, liking, and truth (for reviews, see Jacoby, Kelley, & Dywan, 1989; Kelley & Rhodes, 2002; Schwarz, 2004a). As perceptual fluency increases, judgments of background noise decrease and judgments of fame, familiarity, confidence, liking, and truth increase.

Familiar stimuli are easy to process (if X, then Y), and stimuli that are easy to process seem familiar (if Y, then X). Familiarity is often used as a heuristic cue for judging fame, confidence, liking, and truth. Consequently, even seemingly trivial manipulations of familiarity (e.g., priming, repetition, clarity, rhyming) can increase judgments of fame, confidence, liking, and truth. The truth effect is a particularly interesting case: simple repetition of a product claim increases ratings of the validity of the claim (Hawkins & Hoch, 1992; Hawkins, Hoch, & Meyers-Levy, 2001; Law, Hawkins, & Craik, 1998; Skurnik, Yoon, Park, & Schwarz, 2005). This effect is reduced as the motivation or ability to process information carefully increases or as extraneous sources of feelings of familiarity become more salient.

TEMPORAL INFERENCE

Considerable work has demonstrated the influence of time on people's judgments. A number of temporal biases have been identified, including confidence changes (people become less confident about their own performance ability with the approach of the performance; Nisan, 1972; Gilovich, Kerr, & Medvec, 1993), the planning fallacy (overly optimistic forecasts about the time required to complete a task, such as writing a chapter; Buehler, Griffin, & Ross, 1994; Kahneman & Tversky, 1979), impact bias (overestimating the duration or intensity of one's own emotional responses to an

event (Gilbert, Pinel, Wilson, Blumberg, & Wheatley, 1998; Wilson & Gilbert, 2003), and hindsight bias (seeing a past outcome as inevitable, Fischhoff, 1975; Hawkins and Hastie, 1990). Sanna and Schwarz (2004) provide an integrative account of these phenomena. They find that the subjective ease or difficulty with which memory content comes to mind (accessibility experience, as described above) interacts with the thought content itself to determine the emergence of temporal biases. Specifically, the subjective experience of accessibility made generating few thoughts about success (failure) the same as generating many thoughts about failure (success).

Debiasing efforts (undoing the biased inference phenomena described above) also appear to be influenced by experiences of accessibility, bolstering our confidence in the centrality of experiences of accessibility as a key process in consumer inferences. Confidence changes were effectively eliminated by the thought-listing manipulation. Participants who experienced success-accessibility immediately before their performance showed no decrement in anticipated performance, and participants who experienced failure accessibility when making an initial performance prediction (28 days prior to performance) showed no increment in their anticipated performance. Likewise, the planning fallacy was also reduced when participants felt failure thoughts more easily than success thoughts at a time relatively distant from task completion, but was not completely eliminated when felt-accessibility of success thoughts was increased immediately prior to task completion. The impact bias was also eliminated for anticipated affective feelings about success (when felt-accessibility of failure thoughts was increased well before task performance), and for reactions to failure (when felt-accessibility of success thoughts was increased). Finally, Sanna and Schwarz (2004) eliminated the hindsight bias (with respect to the inevitability of past test performance) when the felt accessibility of thoughts incompatible with actual outcome (failure thoughts for successful performances, success thoughts for failure performances) was increased. Across all of these temporal biases, participants' ability to easily think about alternative outcomes essentially eliminated the bias.

According to Trope and Liberman's (2003) temporal construal theory, temporal inferences and biases are a consequence of different representations of events, depending on the time between the formation of the representation and the event itself. At relatively distant (pre-event) times, individuals' representations of the anticipated event are framed largely in terms of a few abstract features, conveying the perceived essence of the event (high level construals). As the event nears, this representation is dominated by more concrete and incidental details of the event. Trope and Liberman (2003) suggest that these differences in construal may lead to underweighting the feasibility of future decisions.

An intriguing possibility (noted by Schwarz, 2004a) is that the feelings of accessibility are given little (if any) effortful scrutiny by the individuals who hold them, and any resulting inferences are likely made automatically. The inferences themselves may then be used (and disused) deliberately (or automatically, if the decision is familiar and habitual) as inputs into other decisions, with the decision maker blissfully unaware that any feeling of accessibility signaled not the inherent rightness of the decision, but rather a natural (and biased) consequence of information processing.

The temporal inferences discussed here (and others) appear particularly informative for understanding consumer behavior. To the extent that consumer behavior is planned (e.g., planning a vacation, saving for college, gathering information for a future purchase of a consumer durable) any inference that changes solely with the passage of time is fair game for investigation. What may be disheartening to theorists who posit the ability of consumers to make informed, rational decisions (not to mention the consumers themselves) is the image of feelings of accessibility (likely induced by advertising and other tools under the control of marketers) undermining not only the appearance of a rational process, but the ability of consumers to learn from even failed consump-

tion (e.g., the hindsight bias; “the product was bound to fail.” Even if our focus is only on product-related inferences (e.g., the need for a product in the future), how long a product will last, the need for a product warranty, the ease of use (and construction) of a product) the potential impact of temporal inferences is wide ranging and profound, and ignored at the peril of both the marketer and consumer.

SUMMARY

Consumers frequently need to go beyond the information given to make sense of limited or incomplete information about products and services. Consumers use a wide variety of implicit theories to form if-then linkages that associate information (e.g., cues, heuristics, arguments, knowledge) to conclusions in a manner that seems logical or plausible. Plausibility judgments are influenced most heavily by causal inferences, followed by missing attribute inferences, and lastly by temporal inferences (Connell & Keane, 2004). Implicit theories have an important influence on all three types of inferences. Causal inferences depend on implicit theories about dispositions, motivation, ability, and control. Missing attribute inferences are determined by implicit theories about interattribute correlations (e.g., price-quality inference or inference based on presumed correlations between any two attributes), categories (e.g., categorical knowledge about the products produced by various countries or manufacturers), accessibility experiences (e.g., feelings of the ease with which relevant information can be retrieved from memory or constructed based on pieces of information stored in memory), and perceptual fluency (e.g., feelings of familiarity). Temporal inferences are also influenced by implicit theories about accessibility experiences, as well as by construal levels. Different implicit theories can lead to different conclusions, and, consequently, it is important for future research to identify the various implicit theories that are held by consumers and to specify the conditions under which each implicit theory is likely to be accessed and used. Future research should also make use of the response latency, recognition confidence, cued recall, word stem completion, and relearning procedures for measuring spontaneous inference formation to guard against drawing erroneous conclusions based on measurement-induced consumer inferences.

Effects of Sensory Factors on Consumer Behavior

If It Tastes, Smells, Sounds, and Feels
Like a Duck, Then It Must Be A . . .

JOANN PECK

University of Kentucky

INTRODUCTION

As Colleen arrives at the entrance of the store, she scans the inside noticing the layout of merchandise, where the sales racks are located, and the table of sweaters just to the left of the entrance. She then hears the screaming of a baby in a stroller and the customer complaining to a sales person that a blouse she had purchased was the wrong size. At the same time, Colleen takes a sip of coffee from the Caribou store next door, notices the scent of flowers in the air, while she moves toward the table of sweaters. Picking up the pale blue sweater she strokes the collar and is impressed by the softness of the cashmere fabric. All of Colleen's impressions occur within seconds as she makes decisions about whether to remain in the store or move along to another shopping experience. Yet contained in those brief seconds was an integration of her "windows to the world" through her five senses. Our judgments about a store, its products, and even its personnel, are driven in part by the smells we encounter (our olfactory system), the things we hear (our auditory system), the objects we come into physical contact with (our tactile system), our taste experiences (the gustatory system), and what we see (the visual system).

Consumer research has approached the study of consumer behavior from a wide and varying set of perspectives. The chapters in this book provide a synthesis of these perspectives and the research that has followed. Among these perspectives is how information in the environment relates to the forms in which it is received and processed by individuals. Particularly for the latter, is how the perceptual system is organized to receive inputs in different forms or senses. The primary human senses consist of smell, taste, hearing, touch, and sight. Although each of these is a potentially

important system for the processing of information, the sense of sight has perhaps received the greatest amount of attention and is discussed in a separate chapter (see Petrova & Cialdini, chapter 19 of this volume). In this chapter, we narrow our focus on the varied effects of the remaining four senses.

In psychology and the cognitive sciences, perception is the process of acquiring, interpreting, selecting, and organizing sensory information (Grohol, 2005). Perception is one of the oldest fields within scientific psychology. Many cognitive psychologists hold that, as we move about in the world, we create a model of how the world works. That is, we sense the objective world, but our sensations map to percepts, and these percepts are interpreted within the context of the environment we find ourselves in, such as the atmospherics of our store example. As we acquire this new information and consider it relative to the knowledge we have in memory from prior experiences, our perceptions shift as we select further pertinent information to aid our judgments and purchase decisions.

In this chapter, we examine research in the field of consumer behavior published over the past twenty five years on four of the senses. We first examine research on smell and the olfactory system, followed by a discussion of past research on the sense of taste (gustatory), then research on hearing, particularly music, (auditory), and finally research on touch (tactile and haptic system). We then discuss areas where future research might be directed, particularly in terms of implications for the study of individual differences, the role of mental imagery, the promise of more neurocognitive approaches, and the need for more consideration of the multi-sensory interactions of our senses on consumption behavior

METHODOLOGY

A search of articles concerning the senses of taste, hearing, smell and touch was performed through an examination of seven journals that are primarily, or in part, focused on the study of consumer behavior. A total of 81 articles were compiled from the *Journal of Consumer Research* (24 articles), the *Journal of Marketing Research* (15 articles), *Journal of Marketing* (9 articles), *Journal of Consumer Psychology* (10 articles), the *Journal of Business Research* (14 articles), the *Journal of Retailing* (7 articles) and *Psychology & Marketing* (2 articles). The most researched sense is the auditory sense (33 articles) with the majority of this research examining some form of music. Taste follows with 24 articles, smell with 14 and finally, touch with 10 articles. Interest in sensory research appears to be growing, with only 6 of the research articles published before 1980, 18 articles published in the 1980s, 29 in the 1990s and 28 articles in the last 5 years.

REVIEW OF PAST RESEARCH ON SENSORY FACTORS

Sense of Smell

The olfactory sense, or the sense of smell, has been the subject of study in several papers published in the marketing field. While some previous studies have looked at the scents of specific products (e.g., Schmitt & Shultz, 1995, men's fragrances; Schneider, 1977, package fragrance), research in the past ten years has focused on ambient scent. Ambient scent is defined as a scent that is present in the environment but not emanating from a particular object. In general, various scents have been classified by the affective quality of the scent (e.g., how pleasing the scent is), the arousal level of the scent (how likely it is to evoke a physiological response) and the intensity of the scent (e.g., how strong it is). Spangenberg, Crowley, and Henderson (1996) extensively pretested 26 individual scents and separated them into the affective dimension and the arousing or activating dimension

and found that the affective dimension explained most of the variance. In this same paper, Spangenberg et al. (1996) manipulated the scent affect (neutral vs. pleasing) and scent intensity (low, medium, high) with an additional control group. The authors found that whether the scent was neutral or pleasing did not matter, nor did the intensity of the scent, compared to the control, no scent condition. Subjects in the scent condition perceived that they had spent less time in the store compared to the no scent condition. In addition, subjects in the no scent condition perceived having spent significantly more time in the store than they actually did. Subjects in the scented condition did not show this discrepancy. Evaluations of the store overall and of the store environment were more positive when the store was scented versus not scented. Authors found mixed evidence of scent on specific product evaluations and suggest that the congruency of product and scent may be an important dimension for further study.

This notion of congruency has been pursued by other researchers. Mitchell, Kahn, and Knasko (1995) manipulated whether the ambient odor was congruent with a product category. In the congruent conditions, a chocolate scent was paired with a candy assortment choice and a floral scent with a flower arrangement choice. When the odor was congruent with the product class, subjects spent more time processing the data, generated more self references, were more likely to make additional inferences and were more likely to exhibit variety seeking behavior. Interestingly, the researchers found no main effect of scent versus no scent. In general, cognitive elaboration was greater in the congruent conditions.

Scent and Music

In another variant of congruency, two studies concerning the interaction of scent and music have been conducted. Mattila and Wirz (2001) manipulated scent arousal (no scent, pleasant low arousal, and pleasant high arousal) and music arousal (no music, pleasant low and high arousal music) and examined whether scent and music were matched on arousal level or mismatched. When scent and music matched in terms of arousing qualities, consumers satisfaction with the shopping experience, approach behavior and impulse buying were significantly higher than in the mismatched conditions. This was true of both the high arousal match (scent of grapefruit and fast tempo music) and low arousal match (scent of lavender and slow tempo music). Spangenberg, Grohmann, and Sprott (forthcoming) also examined the effects of ambient scent and music by using a Christmas theme. They set up a lab experiment and manipulated scent (no scent vs. Christmas scent) and the type of music (non-Christmas music vs. Christmas music) in a mock retail store. Similar to previous research, they found that the matched condition of Christmas scent and Christmas music resulted in more favorable evaluations for the store, its merchandise, the store environment, and intentions to visit the store. When music and scent did not match, evaluation and behavior intentions were not affected, or, in some cases, negatively affected.

Scent and Other Moderators

Michon, Chebat, and Turley (2005), in the context of a field experiment varied scent along with retail density (how crowded the mall was) and examined shopper's perceptions of product quality, mall environment and positive affect. The authors found a u-shaped relationship in that the positive effect of ambient scent on shoppers' perceptions of the mall atmosphere was observed only at the medium retail density level. Further, a favorable perception of the retail environment influenced the perception of product quality. Shoppers' mood did not have a significant direct effect on the perceptions of product quality.

Morrin and Ratneshwar (2000, 2003) crossed ambient scent (unscented, pleasant) with brand familiarity (familiar, unfamiliar) and examined the evaluation, attention, and memory for familiar and unfamiliar brands. The authors (Morrin & Ratneshwar, 2000) found that a pleasant ambient scent improved evaluations for objects that were not as familiar or well liked. However, they were concerned about potential ceiling effects for the familiar brands as well as allowing only a 5-minute delay before the memory measures. In their subsequent research (Morrin & Ratneshwar, 2003), the authors examined the memory effects in more detail to determine if ambient scent influences memory of brands at encoding, retrieval, or both. In a two-phase experiment, 24 hours apart, the authors manipulated ambient scent (no scent, scent congruent to household cleaning products (geranium), scent incongruent to household cleaning products (clove)) and brand familiarity. In Study 1, the same scent was used at encoding and retrieval and it was found that ambient scent improved recall and recognition of familiar and unfamiliar brands. This was true whether or not the scent was congruent with the product category. In Study 2, the authors manipulated whether the scent was present at encoding or retrieval and found that the enhancement of brand memory was due to the presence of an ambient scent at encoding rather than retrieval. The ambient scent increased attention in terms of longer viewing times.

Process Explanations

Why does ambient scent influence consumer behavior? The two explanations most often used can be separated by whether scent primarily influences affect such as mood or whether a scent primarily influences cognition. In the area of retail atmospherics, Mehrabian and Russell (1974) discuss mood as a mediating factor between environmental cues and behavior. The environmental psychologists assert that shoppers react to environmental cues with approach (e.g., desire to stay in the environment, explore, etc.) or avoidance (e.g., desire to leave) behaviors and that mood mediates this relationship. However, in the marketing literature, this explanation has not received strong support. Bone and Ellen (1999), in a review article, found that only a small percentage of studies (16.1%) showed any influence of scent on mood. Another process explanation is that scent influences cognitive processes. Morrin and Ratneshwar (2003) found no effect of scent on mood, but found that scent increased attention to brands as measured by viewing times of various brands (Morrin & Ratneshwar, 2000, 2003). Mitchell et al. (1995) found that scent influenced the extent of information processing and cognitive elaborations. Chebat and Michon (2003) tested various process theories and concluded that cognitions pertaining to product quality and the shopping environment are influenced by scent, which in turn influenced the mood of the shopper. Hirsch (1995) examined the effects of ambient odors in a Las Vegas casino. While the specific odors used are not identified in the research, the author found that an ambient odor significantly increased slot-machine usage. The author suggests (but does not test) a cognitive process whereby the odor may have induced nostalgic recall of memories which enhanced the gambling mood. There seems to be more support for the influence of scent on cognitive processes but, given the interaction between cognition and affect, this is clearly a complicated question. Bone and Ellen (1999) suggest that accessibility and availability theories may be a more useful theoretical basis for understanding ambient scent research. We next turn to a discussion of past research in consumer behavior and marketing on the sense of taste.

Sense of Taste

Research on the sense of taste (or the gustatory sense) is quite varied and includes administration of taste tests, changes in taste as it relates to new product formulations, store-sampling, branding,

packaging and taste as a form of direct product experience. Each of these topics will be discussed in turn.

Taste Discrimination

At the most basic level, some researchers have examined various methods of administering taste tests (e.g., Buchanan, Givon, & Goldman 1987). One of the key issues is to identify which type or method of taste test can best determine an individual's ability to discriminate between different tastes. This is important to marketing for several reasons. In some instances, a manufacturer may want to test the similarity of two alternative product formulations to assess the consistency of taste from batch to batch of a product. Often, these tests involve in-house trained experts (Greenhalgh, 1966). Also, a taste test may be used to identify consumers who have greater ability to discriminate products by taste or to test alternative formulations. A common test, termed the triangle test asks consumers to identify the one sample of three that is different from the other two, which are identical. Researchers (Morrison, 1981; Moskowitz, Jacobs, & Firtle, 1980) have examined whether subjects who do well on this type of test are actually discriminating between the tastes or are simply guessing. The authors make statistical suggestions for improving the quality of the results of triangle tests.

Another common taste discrimination task involves consumers making several paired comparisons and noting their preferred choice following each comparison. Once subjects have completed several paired comparisons, the consistency of their choices is used to determine their discrimination ability. Finally, a preference rank procedure is used where subjects are given three taste samples, one different from the other two and are asked to rank the three from most to least preferred. A subject who ranks the different sample as most or least preferred is judged to have made a correct choice, regardless of the preference. A subject who ranks the odd sample as between the two identical samples is judged not to have discriminated. In an empirical investigation examining the three procedures, Buchanan et al. (1987) found that the repeated pair comparison method was the most sensitive discrimination task and preference ranking was the least sensitive. The researchers also found that the discrimination ability measured by triangle tests was significantly correlated with that measured by paired comparisons, which supports the validity of the tests.

In the area of product reformulations, Villani and Morrison (1976) investigated a method for estimating demand for a new product formulation and recommended that estimates for current users and non-users be made separately for more accuracy. In arguably the most famous product reformulation, the New Coke experience is discussed by Dubow and Childs (1998). These researchers explain the gradualist approach hypothesis which uses the perception and psychophysical concepts of just noticeable difference (when a consumer can just notice a change) and just unnoticeable difference (where the change is undetectable). In the gradualist approach to product reformulation, the manufacturers would change the taste of a product in a sequence of small, constant, just unnoticeable difference steps so that, at no point would tasters perceive the reformulation differences. Arguing against the gradualist approach hypothesis, the flavor balance hypothesis suggests that a gradualist approach is impossible in a multi-ingredient formula as unexpected interaction effects of various ingredients may be perceptible. Using New Coke and Coca-Cola Classic, Dubow and Childs (1998) conduct an empirical test which suggests that Coke may have been better off using a gradualist approach to reformulation and not announcing the product change.

Taste and Store Samples

The area of taste and sampling food items in stores has also been researched. Johnson, Sommer, and Martino (1985) unobtrusively observed consumer behavior at bulk food bins in fourteen supermar-

kets. The most frequent problem behaviors were consumers using their hands to retrieve products and consumers snacking on products. Not surprisingly, these two problem behaviors were correlated. Besides this unsanctioned behavior of snacking, stores often encourage taste by offering product samples. Steinberg and Yalch (1978) examined obese and nonobese shoppers in a supermarket, how hungry the shoppers were, and the effect of sales of other grocery items when shoppers were offered an in-store sample (a doughnut in the bakery section). For the nonobese, if a shopper was hungry, the food sample seemed to satisfy some of their hunger and they reduced their additional buying compared to the nonobese shoppers who were not hungry. For the obese shoppers, offering a food sample increased additional buying and this was only slightly moderated by their level of hunger. The authors conjecture that obese shoppers are not as sensitive to their internal cues of hunger so offering a sample may have increased further the salience of food and they purchased more.

Some research (Nowlis & Shiv, 2005; Shiv & Nowlis, 2004) looked at whether or not to distract shoppers as they tasted a food sample. Contrary to industry wisdom, these researchers found that distraction of the shopper increased subsequent choice for the sampled food. The authors explain these results using a two-component model in which the ultimate pleasure a shopper derives from tasting a food sample is a function of an informational and an affective component. The affective component involves the emotional responses of the shopper and is associated with relatively automatic processes. The informational component is a more objective feature of the tasting experience and related to aspects such as quality. This information component is comprised of more controlled processes. Distracting a consumer influences subsequent choice by increasing the impact of the affective component.

Taste and Branding

Another area of taste research concerns the relationship between taste and brand name. In an early marketing study, Allison and Uhl (1964) found that, in a blind taste test, experienced beer drinkers (they drank beer at least three times per week) were unable to distinguish their preferred brand from other brands of beer. However, when the brands of beer were identified, these same beer drinkers rated the taste of their preferred brand significantly higher than in the blind taste test. Similarly, Bellizzi and Martin (1982) found that whether a brand was national or generic significantly influenced the taste of the product (national brands ranked higher). Sprott and Shimp (2004) examined the interaction of brand status (store brand, national brand) and quality of the tasting experience. They revealed that sampling a store brand substantially increased evaluation for the store brand compared to the group that did not have the opportunity to taste the product (juice) only if the sample store brand was high quality. No benefit was demonstrated with the national brand. The authors theorize two explanations that may be likely. When consumers make quality judgments, they base these judgments on inherent product features, or intrinsic cues and on extrinsic cues such as price and brand name. Intrinsic cues, such as taste, tend to dominate extrinsic cues when intrinsic cues can be evaluated with confidence at the time of purchase. When intrinsic cues cannot be evaluated (i.e., taste), consumers base their judgments more on extrinsic cues (i.e., brand name). By providing consumers with the opportunity to taste the store brand, an intrinsic cue was provided that influenced product perceptions.

The other theoretical explanation used is schema congruity theory (Mandler, 1982). Schema congruity theory asserts that affect for a particular brand will be most positive when a person perceives moderate incongruity between the product category schema compared to extreme congruity or incongruity. The expected schema for store brands is that they are lower quality compared to

national brands. Participants who tasted the store brand learned that the juice was of high quality and consequently their store brand schema and their actual experience were moderately incongruent, thus resulting in more positive affect compared to the subjects who did not have the opportunity to taste.

LeClerc, Schmitt, and Dubé (1994) examined the effect of foreign branding (French) on product perception and attitudes. In Experiment 3, the authors crossed whether a participant could taste the product (yogurt) with whether the brand was foreign (English, French). They found that with no taste test, a French brand name generated higher ratings on the hedonic dimensions of the product (i.e., pleasantness, sweet, delicious, creamy) and lower ratings on the utilitarian dimension (healthy, wholesome, nutritious). Additionally, a French sounding brand name affected product perception and evaluation even after a taste test but only on the hedonic dimension.

The effect of brand awareness on sampling of brands and choice revealed that when subjects do not have any brand awareness, they tended to sample more brands and were more likely to select the high quality brand (Hoyer & Brown, 1990). If subjects were aware of one brand in a set (this study used brands of peanut butter), they tended to sample fewer brands and tended to choose the known brand even when it was lower quality than other brands in the sample. In a related area to branding, one study on product packaging and taste found that packaging influenced the taste of the product. McDaniel and Baker (1977) examined consumer reactions to identical potato chips placed in a wax coated potato chip bag or a “new” polyvinyl bag. In a blind taste test, subjects rated the chips as identical. However, when the taste test was conducted with the bags, even though the polyvinyl bags were extremely difficult to open (subjects had to use their teeth, stand on the bag and pull, etc.), the chips in the polyvinyl bags were viewed as crispier and tastier. The authors interpret the findings that a negative packaging attribute (hard to open) can enhance product quality perceptions since consumers infer other attributes such as crispier or fresher, even when no difference in the actual product quality exists.

Taste, Direct Experience, and Product Perceptions

Taste can be conceptualized as a form of direct product experience. Smith and Swinyard (1983) researched product trial (tasting a salted snack product) and attitude-behavior consistency. When attitudes were based on the taste of the product, the attitude-behavior correlation was much higher than without this tasting experience. The authors emphasize the information value of direct product experience. Scott and Yalch (1980), using Bayesian analysis, examined consumer acceptance of experiential information about a new product. Consumers who were given a reward for sampling a new product and who were encouraged to attribute their behavior to this situational factor (and thus discount their intrinsic interest in the product) were receptive to unfavorable product information and unreceptive to favorable information. The authors maintain that their research demonstrates a tendency for people to accept information consistent with their perceptions about the causes of their behavior and to reject information when it contradicts these attributions. Similarly, Roberts and Taylor (1975) demonstrate that even with a tasting experience, it is difficult to change consumer’s previously held perceptions.

Some researchers consider that product trial through tasting can be diagnostic and influence perceptions and choice. Levin and Gaeth (1988) vary the temporal order of tasting a product (before or after reading a ground beef label) and the valence of the label information (positive, 75% lean; negative, 25% fat). The framing effect of the labeling was reduced when consumers sampled the product compared to when they did not. The authors note that product experience will have greater weight when it is unambiguous or diagnostic. Also, using diagnosticity, Pechmann and

Ratneshwar (1992) varied the diagnosticity of a taste test as well as the objective correlation of price and quality. Four samples of orange juice varying in quality were used. In one condition taste was perfectly correlated with price and in another the correlation was zero. Diagnosticity of the taste test was manipulated by either allowing participants to go back and forth between the four samples (high diagnosticity) or by presenting the samples sequentially with some time in between and no opportunity to go back to previous samples (low diagnosticity). It was found that prior beliefs biased judgments of the samples less when diagnosticity was high rather than low (Study 1). When subjects were allowed to use a memory aid (Study 2), they tended to be relatively accurate in their judgments, even though they had the same constraints as the low diagnosticity subjects in the first study. The authors conclude that the degree to which prior beliefs and actual direct taste experience are used depends on the diagnosticity of the mental representations of the taste experience. The higher the diagnosticity, the greater the impact of the actual taste experience relative to prior beliefs. The lower the diagnosticity, the greater the impact of prior beliefs relative to the actual taste experience.

Braun (1999) looked at a different aspect of taste and memory. She asked the question of whether advertising received after a direct product experience (tasting orange juice) altered how consumers remember their experience. This research found that consumer recall of a past direct experience with a product (tasting) was subject to distortions. Post-experience advertising made consumers think they had tasted a better tasting juice by altering their memories of the tasting experience through advertising. Altering the time between the tasting experience and the advertising exposure, this research revealed that the post experience is working at the memory reconstruction phase of recall rather than as a source confusion problem at encoding. Another study found that imagining a taste experience, even of a hedonic product (ice cream) may actually be a more affective experience than actually eating the product (Compeau, Grewal, & Monroe, 1998).

Taste as More Incidental

In some reach, the actual product tasting is not a key part of the research question yet product taste plays a role. Maison, Greenwald, and Bruin (2004) used a Coke-Pepsi taste test in a pretest to determine subjects who could identify each of the brands in a blind taste test. The primary focus of this research was to compare the predictive validity of implicit versus explicit preferences for brands. When separating subjects by their ability to identify Coke or Pepsi in a blind taste test, this research found that subjects who exhibited higher taste discrimination in the blind taste test had more extreme implicit preferences. This research suggests that implicit preference measures are more sensitive measures of preference than explicit preference measures.

Kahn and Isen (1993) did not include actual tasting in their study, but rather taste perceptions. They found that a positive affect manipulation increased variety seeking behavior relative to the control when unpleasant or negative features of the items were not made salient. However, when salient negative features were introduced into the choice set with the inclusion of products that potentially tasted bad (i.e., low salt and high fiber crackers—Experiments 1 and 2), or by alerting subjects to the negative health risks of familiar items (Experiment 3), there was no difference between positive affect and a control group on variety seeking behavior. We next turn to the discussion of research on hearing or auditory effects on consumer behavior.

Sense of Hearing

The auditory sense or hearing has been studied in marketing mostly in the context of background music in advertising and in retail stores. Researchers have examined the effects of music on con-

sumers' moods, product evaluation and choice, fit with an ad or store, time perceptions, and as part of a retail store's atmosphere. A few studies have examined non-music elements such as voice pitch and the interaction between auditory information and visual information. First, the auditory sense as it relates to music in marketing will be discussed followed by studies concerning the interaction between audio and visual information.

Music and Mood

Bruner (1990), in a review article on music and mood, stressed the complexity of music and its influence on individual's moods. Bruner also provided a taxonomy of musical elements and the emotional expressions ascribed to each structural element. The three main structural features of music are tempo or time of the music (how fast or slow it is), pitch related characteristics (includes major, minor keys), and texture (includes volume, instrumentation). (Please see Bruner, 1990, Appendix, p. 102, for a more complete description of the elements.) Bruner stressed that people assign emotional meaning to music and experience affective reactions. For example, fast music is considered happier than slow music. Kellaris and Kent (1994) identify three basic musical properties similar to those of Bruner (1990) which are tempo (fast, moderate, slow), tonality (major, minor, atonal) and texture (classical, pop). These authors produced original compositions with digital sound technology to provide orthogonal manipulations of the three structural properties of music. They also identified three dimensions of response (pleasure, arousal, and surprise) that were elicited by the three properties of music. They call for a better understanding of the multidimensional nature of both musical stimuli and listener response. Similarly, Scott (1990) advocated using an interpretist approach in research to understand the complexity of consumer meaning and response to music.

In one study in marketing, Gorn (1982) used classical conditioning and illustrated that hearing liked music (music from the movie *Grease*) or disliked music (classical Indian music) while being exposed to a product (a pen) can directly affect product preferences as measured by product choice. Both Kellaris and Cox (1989) and Allen and Madden (1985) attempted to replicate Gorn (1992) but failed to do so. Kellaris and Kent (1994) note that Gorn (1992) did not control for the different structural properties of music. They argue that when fast tempo, upbeat music is used to operationalize the positive unconditioned stimulus, the valence of the music may have been confounded with the arousing quality of the music which may have altered the level of attention of participants. In classical conditioning, music is assumed to induce a mood which is directly transferred to the product.

The influence of music on mood states and new product evaluations was researched by Gorn, Goldberg, and Basu (1993). Mood was manipulated by music to induce either a good or a bad mood and subjects' awareness of the music as a source of their mood was also manipulated. When subjects were not aware of the source of their mood, their mood biased their evaluations of the product so that the product was evaluated more favorably when in a good mood than when in a bad mood. However, when subjects were made aware of the source of their mood (the music), there was no difference in product evaluations between those in a good or bad mood. The authors explained the results with a mood-based cognitive heuristic "How do I feel about it?" (Schwarz, 1990), which suggests that people observe their own feelings and draw conclusions from them. If a person is not aware of the source of their mood, they assume the feelings are information to be used in product evaluation.

Music was also used to induce either a pleasant or unpleasant affective state and examine its interaction with the affective tone of an advertisement (Gorn, Pham, & Sin, 2001). While controlling for arousal (Study 1), music was used to manipulate a pleasant or unpleasant affective state. In Study 2, both arousal and pleasure were manipulated with music. Results showed that the valence

of a person's affective state influenced judgment in a mood congruent direction especially if an ad had an ambiguous affective tone. The arousal dimension, but not the valence dimension, influenced ad evaluations. Ad evaluations were more polarized in the direction of the ad's affective tone under high arousal than under low arousal.

Dubé and Morin (2001), in a field setting, examined the pleasure induced by music (measured, not manipulated) and its impact on store evaluations. No main effect of pleasure intensity induced by music on store evaluations was found and they explain that there was no support that mood induced by music directly influenced store perceptions. Instead, this is mediated by attitude toward the servicescape and attitude toward the sales personnel.

While the preceding studies focus on the influence of music on mood, some researchers have examined the cognitive processes resulting from background music. Olsen (1997) manipulated whether background music was present (2 levels, silence and music) and the amount of time between consecutive information presented in ads (0, 1, 2, 3, second) in two studies. Relative to silence, background music hindered recall when information was presented at 2 seconds or shorter but enhanced recall at 3 seconds. Using a resource matching explanation (cf. Anand & Sternthal, 1990), music had a detrimental effect on recall at shorter times because it distracted cognitive resources from the rehearsal of brand information thereby hindering attention. As cognitive resources increased to the point when those available matched those required, information was sufficiently processed and a higher level of recall was exhibited.

Music and Congruence

Park and Young (1986) examined the effect of music (present, absent) and three types of involvement (low involvement, cognitive involvement, affective involvement) on the formation of attitudes toward a brand in the context of TV commercials. Music increased the brand attitude for subjects in the low involvement condition but had a distracting effect for those in the cognitive involvement condition. Its effect for those in the affective involvement condition was not clear. They argue that music acted as a peripheral persuasion cue.

While the notion of fit was not specifically studied in Park and Young (1986), the music was selected since it was "best suited" for the commercial. MacInnis and Park (1991) examine two dimensions of music including its fit with the ad and the extent to which it arouses emotion laden memories. Fit was defined as a participant's perception of the music's relevance to the central advertising message. These two dimensions of music were fully crossed with two levels of involvement. The emotion laden quality of the music had similar effects on attention to the music and affective response for both high and low involvement participants. Yet, it had different effects on their message based processing. For low involvement participants, the emotion laden quality enhanced message processing while it seemed to distract high involvement participants from processing the message. Similarly, while fit had similar effects on high and low involvement participants by focusing attention on the music and the message, it created different effects on their affective responses. Lack of fit created more negative emotions for low than for high involvement participants. An unexpected finding of this research was the strong impact of fit on both positive emotions and attitude toward the ad.

Kellaris, Cox, and Cox (1993) examined the fit or congruency of music and the message (low, high) and the attention getting value of music (low, high) along with a no music control group. The dependent measures consisted of recall and recognition of brand names and message arguments in the context of a radio ad. This research found that when background music was congruent, attention getting music increased recall and recognition of brand names. When the music was atten-

tion getting and the message incongruent, it pulled listener's attention away from the message and negatively influenced recall. The no music ads performed as well or better than the musical ads in terms of recall and recognition.

The relationship between the fit of the mood induced music (happy/sad) and the purchase occasion (happy/sad) and its effect on purchase was studied by Alpert, Alpert, and Maltz (2005). While mood induced by music did not exhibit a main effect on purchase intentions, its interaction with fit was significant. The authors conclude that when music is used to evoke emotions congruent with the symbolic meaning of the product, the likelihood of purchase is increased.

Music and Tempo

Music is a key element in determining the atmosphere of a service or retail environment. Numerous studies have examined the role of music in these settings. Milliman (1982, 1986) researched the influence of background music tempo in a supermarket and in a restaurant. In the supermarket study, Milliman (1982) varied the tempo of classical music (fast, slow) and found that the pace of the in-store traffic was significantly slower with slow tempo music compared to fast tempo music. Also, higher sales volume was associated with slower tempo music and lower sales figures were associated with faster tempo music. Interestingly, when shoppers were asked about their awareness of background music, the majority of participants were not sure if music was in the background or they were incorrect. In the context of restaurant dining, Milliman (1986) varied the tempo of the background music (slow, fast) and found that with slower music, patrons stayed longer, ate about the same amount of food but consumed more alcoholic beverages. The author conjectured that the slower, more relaxing environment created a greater approach condition for the diners.

In the context of a travel agency service, participants viewed a video in which the four music conditions varied in the arousal quality through changes in tempo (Chebat, Chebat, & Vaillant, 2001). The classical music was pretested to be equally pleasurable. This research found that highly arousing music hampered cognitive activity and the authors argue that the "fit" between the highly arousing music and their context of the message from the travel agency was low. Similar to MacInnis and Park (1991), this study showed that when highly arousing music drew attention to itself, the effect was to reduce cognitive resources available for information processing and also reduce recall. In contrast, the slow tempo music did not attract attention to itself and did not interfere with the cognitive resources used to process the message. However, the authors caution that the deeper the cognitive activity, the more negative the attitude toward the employee and toward the visit.

Music and Atmospherics

Several studies have not simply manipulated an aspect of music but rather manipulated the image or atmosphere of a retail setting with music as an element. For example, Meyer (1981) manipulated the décor of a pizza restaurant and had an elaborate décor condition, which included live music, or plain décor condition with no music. The purpose of the research was not related to music but was to advance a model for the study of consumer evaluation of choice alternatives given uncertainty about the alternative and attributes.

Using videotape technology, Baker, Levy, and Grewal (1992) combined music and lighting to manipulate ambient cues in a retail environment. They found that ambient cues (low and high) interact with social cues (number and friendliness of employees) to influence shoppers' pleasure and subsequently their willingness to purchase. Again, music is confounded with lighting making the results from music alone impossible to interpret. Finally, while not the main focus of their

study, Grewal, Baker, Levy, and Voss (2003) use classical music versus no classical music as one manipulation in the atmosphere of a jewelry store. (The number of store employees and the number of customers was also varied). Results found that classical music had a positive effect on store atmosphere and, in turn, intentions to shop at the store. The authors also point out that classical music “fit” with the jewelry store.

Schlosser (1998) manipulated music along with other components in order to operationalize a prestige and a discount condition. In the prestige condition, the store was described as having classical music, soft lighting, hardwood floors, and wide aisles; in the discount condition the music was top 40, the floors were linoleum, and the aisles were narrow. The primary conclusion from this research was that different types of products are differentially affected by the atmosphere of a store. Products were divided by whether they have a utilitarian function (more related to product performance) or a social identity function (more related to the expression of self-concept). Store atmosphere influenced perceptions of social identity products but not utilitarian products.

Music and Time Perceptions

Time perceptions are an active area of research in marketing. In the area of retail atmospherics Yalch and Spangenberg (2000) used a simulated shopping experiment and varied whether the music played was familiar or not. Participants reported shopping longer when exposed to familiar music but they actually shopped longer when exposed to unfamiliar music. The shorter actual shopping times in the familiar music condition were related to increased arousal. Emotional states were not directly related to the music manipulation.

Besides familiarity of music and time perceptions, researchers have looked at the valence of the music and time perceptions. Kellaris and Kent (1992) varied the tonality of the music (major, minor, atonal) and used a synthesizer so that other aspects of the music were equal. The music in a major key was positively valenced while the atonal music was negatively valenced. Results showed that perceived duration was the longest for participants exposed to positively valenced music and shortest for those exposed to negatively valenced music. They used Ornstein's (1969) storage size model to account for the findings. This model suggests that perceived time duration is a function of the amount of memory dedicated to storing stimulus information encountered during a given interval. Larger allocations of memory space are associated with longer perceived time durations. The relative pleasantness of the major key music motivated listeners to devote more attention to the music and allocate greater cognitive resources to processing it. This may have both reduced the allocation of processing to some internal clock used to judge the duration of an event and created the perception that more stimulus information was heard.

Hui, Dubé, and Chebat (1997) had people watch a video of a person waiting in line at a bank and varied the valence of the music. Results demonstrate that positively valenced music increased the perception of wait duration compared to negatively valenced music (similar to Kellaris and Kent, 1992) and compared to the no music condition. But, they note that the perceived wait time did not have a negative impact on attitude toward the service organization (the bank). In fact music, regardless of its valence, made the service environment seem more positive to customers waiting in lines. Related to this finding, Cameron, Baker, Peterson, and Braunsberger (2003) manipulated valence of music and found that while music likeability influenced both wait length evaluations and mood, only mood contributed to participants' evaluation of their overall experience. So, even though positively valenced music may influence wait length duration perceptions negatively, it also impacts mood positively and mood influences the overall evaluation of the experience.

In a field study concerning telephone wait times, music was used as one of the conditions to fill silence when people were waiting on a phone (Antonides, Verhoef, & VanAalst, 2002). Besides

playing music, other conditions included wait duration information, queue information, or silence. Music had a significantly positive effect on the evaluation of the wait but did not influence the perceived duration of the wait.

Voice Characteristics Auditory Research

While the overwhelming majority of auditory studies in marketing involve music, there is some research examining other aspects of hearing. Both MacLachlan and Siegel (1980) and Chattopadhyay, Dahl, Ritchie, and Shahin (2003) investigated aspects of announcer speech. MacLachlan and Siegel (1980) found that a 25% time compression of TV commercials increased unaided and aided recall. However, they note that voice pitch was not changed with the compression. Chattopadhyay et al. (2003) varied three characteristics of announcer speech: voice pitch (high, low), syllable speed (normal, high), and pause length (normal, short). A voice with faster than normal syllable speed and low pitch produced less negative advertising directed cognitive responses and more favorable attitudes toward the ad and toward the brand. No significant results were found for pause length suggesting that participants had sufficient opportunity to process the information. Instead, the authors suggest that while the opportunity to process did not diminish with increased speed, the motivation to process did.

Auditory and Visual Processing

Using hemisphere specialization, Anand, Holbrook, and Stephens (1988) transmitted instrumental music to one ear of participants and verbal text in the other ear. Results showed that there was increased affect toward familiar stimuli and toward words transmitted to the right ear and music transmitted to the left ear. The authors argue that this evidence supports a cognitive affective model in which affective responses are formed with cognitive mediation rather than the independence of the affective and cognitive systems.

In the context of product placement, Russell (2002) examined the modality of presentation (auditory, visual) of the product placement as well as the connection between the plot of a show (more or less connected). An auditory placement refers to the brand being mentioned in the dialog of the show while a visual placement is the appearance of the brand on the screen. The author stated that since the auditory channel carries the plot of the show, it is inherently more meaningful than the visual channel in the context of product placement. Thus, a congruent modality/plot connection exists when either the product placement is audio and the product is integrated into the plot of the show or the product placement is visual and the connection to the plot is minor. A product/plot mismatch occurs when either the placement is audio and the product is not integrated into the plot or the placement is visual and the product is integrated into the plot. Memory improved when the modality and plot connection were incongruent but persuasion was enhanced by congruency. Incongruent placements adversely affected brand attitudes because they seemed out of place and were discounted.

The effects of presentation modality (audio, visual) along with the modality of imagery (audio, visual) and the influence on learning was researched by Unnava, Agarwal, and Haugtvedt (1996). Results showed that there was greater advertising recall when the presentation modality differed from the imagery modality. The cognitive resources that were used in the process of imaging were the same that were used in perceptual tasks of the same modality so mutual interference between imaging and perceptual tasks inhibited message learning. In a related study, Costley, Das, and Brucks (1997) asked the question of whether the modality of the retrieval cue (audio or visual) affects the recall of information originally presented in the same versus different modalities.

Support was found for a “modality match” hypothesis in which retrieval cues enhance recall better within modality rather than across modality. Results are explained using the encoding specificity principle (Tulving & Thomson, 1973). This principle states that the likelihood of recall improves as the features present in the environment when the memory is encoded match those present in the retrieval environment. Features can include aspects of the stimulus context such as the modality of the information presented.

Tavassoli and Lee (2003) examined auditory and visual elements in advertising in the context of Chinese logographs (which rely more on visual processing) and English works (which rely more on audio and sound based processing). Findings indicated that auditory elements interfered more with the learning of and cognitive responding to English ad copy than with Chinese copy and vice versa for visual elements. However, auditory elements are better retrieval cues for English than for Chinese copy and vice versa of visual elements. The authors concluded that non-verbal elements in advisements such as auditory cues can compete for cognitive resources during message encoding but can also serve as effective memory cues. While music was not the focus of this research, various forms of music were used throughout the three experiments.

In one study, preschoolers and school aged children were used to examine information presented using audio messages and visual messages (Macklin, 1994). Children that only heard the information and children who only saw the information performed equally well on learning (there was no visual superiority effect). However, presenting information both visually and by audio was the most effective. When incomplete visuals were presented, school aged children had the ability to imagine the remainder of the visual while preschool aged children could not. The author argues that a critical element in processing is the comprehensibility of the information rather than the modality.

Sense of Touch

The sense of touch, or haptics (touch with the hands) has historically been the least studied sense in marketing. Perhaps the rise of online and catalog shopping, and an inability to physically examine products prior to purchase has spurred this area of research. The primary categories of touch and haptic research include the differences in product attributes that encourage touch, individual differences in the motivation to touch, and situational influences that encourage touch. Finally, one research study examined the interaction between vision and touch and the elongation bias. Each of these areas will be discussed.

Touch and Product Differences

Products differ in whether consumers will be motivated to touch them prior to purchase. Touch excels at ascertaining what Klatzky and Lederman (e.g., Klatzky & Lederman, 1992; 1993) call material properties which include texture, softness, weight, and temperature. If a product category varies in a diagnostic way on one of or more of these attributes, consumers will be more motivated to touch the product prior to purchase. For example, clothing varies on texture and weight and will likely encourage pre-purchase touch more than books or CDs, which do not vary on material properties in a diagnostic manner. Since marketing uses many self-report measures, Peck and Childers (2004) asked the question of whether participants’ verbal reports actually correspond to their behavior in the area of touch and product evaluation. They videotaped the hand movements of participants as they concurrently verbalized during product evaluations. They found that in the area of behavioral reports and actions, there was correspondence between what people say and what

they do. Product categories that varied most in material properties (e.g., sweater, tennis racket), were touched longer than those that varied somewhat (e.g., calculator, cell phone) and these were touched longer than categories with no diagnostic material properties (e.g., cereal, toothpaste).

Another logical question to ask is whether consumers can be compensated for an inability to touch a product during evaluation. Holbrook (1983), when using sweaters as stimuli for study, noted the strong role played by tactile cues when participants were evaluating the product. He encouraged using, or at least being aware of using, actual products compared to visual representations of products such as pictures in research. McCabe, Brown, and Nowlis (2003) varied whether the products differed on material properties and whether participants had the actual product to evaluate, a picture of the product, a list of attributes, or some combination. The primary dependent variable was purchase likelihood. Results showed that product categories that vary in the diagnosticity of touch (e.g., bath towels, carpeting) were more likely to be preferred in shopping environments that allow physical inspection than in those where touch is unavailable. However, there was no difference in the preference of products across the shopping environments (touch, no touch) when a product category did not vary on material properties (e.g., videotape, rolls of film) since for these categories, vision was diagnostic. Results also found that the differences in preference between the two environments were reduced when the material properties of the products were verbally described. In effect, compensation for lack of touch was possible with a written description (see also, Peck & Childers, 2003a).

Touch and Individual Differences

Peck and Childers (2003a) also examined whether compensation for lack of touch was possible and considered the type of material properties to be compensated for as well as an individual difference in the preference for touch information. They conjectured that not all material properties create the same type of response in consumers. Specifically, the pleasant sensory feedback experienced when assessing softness may differentially influence the person touching compared to a more functional material property such as weight. In addition, they considered an individual difference in the preference for touch information. Peck and Childers (2003b) developed the Need for Touch scale (NFT) and tested the scale in seven studies. NFT is defined as a preference for the extraction and use of information obtained through touch. It includes two dimensions, an instrumental and an autotelic dimension. The instrumental dimension of NFT refers to those aspects of touch that reflect outcome directed touch with a salient purchase goal. The image of a consumer involved in instrumental touch is that of a problem solver consciously engaged in the goal directed activity of searching for information and arriving at a final judgment. The other dimension of NFT is the autotelic factor. Autotelic touch involves a consumer seeking fun, sensory stimulation and enjoyment with no purchase goal necessarily salient. The autotelic factor is defined as the enjoyment and affect of touch along with the compulsive or irresistible urge to explore via touch.

Peck and Childers (2003b) found that NFT moderated the relationship between direct experience and confidence in product judgments. For individuals higher in NFT, a lack of direct experience (an inability to touch) resulted in less confidence in the judgment. For low NFT individuals, confidence in judgment was unaffected by a barrier to touch provided there was a clear visual of the product. In a related study on compensation and an inability to touch products, Peck and Childers (2003a) found that high NFT participants were more confident and less frustrated when they could touch to evaluate products where low NFT subjects' confidence in judgment did not change on the basis of whether they could touch the product. The researchers also found that for individuals high in NFT, compensation for an inability to touch was possible. For more functional haptic

information, such as weight, a written description compensated for the inability to touch. However, for a material property with pleasant sensory feedback (softness), a written description did not provide this compensation. In effect, there are certain types of product attributes for which there is no substitute for actual touch. Low NFT subjects required a visual cue and the authors conjecture that visual information compensated for actual haptic exploration.

Similar to the instrumental dimension of Need for Touch, Citrin, Stem, Spangenberg, and Clark (2003) developed an individual difference scale titled, "Need for Tactile Input," and found that it was negatively related to products purchased over the internet, especially those categories that vary with respect to material properties. They also found that women showed a higher Need for Tactile Input than men.

An individual difference in the preference for touch information has been found to moderate the time touching products to ascertain information (Peck & Childers, 2004). Specific stereotypical hand movements termed EPs (exploratory procedures) have been linked to the haptic perception of material properties. For example, when individuals need to assess texture, they engage in the lateral motion EP which consists of rubbing the fingers back and forth across the surface of the objects. Peck and Childers (2004) videotaped subject's hand movements as they were evaluating products. They found that for all material properties except texture, high NFT individuals spent less time exploring with their hands than did individuals low in NFT. The authors note that since touch information is more accessible for high NFT individuals, they are more efficient at extracting this information. Higher accessibility of haptic information for high NFT individuals was exhibited thorough a free recall exercise and through a timed response measure (Peck & Childers, 2003b). However, since texture provided a pleasant sensory feedback (a soft sweater), high NFT individuals spent a longer time assessing texture than their low NFT counterparts.

Touch and Situational Factors

While the forgoing research involved judgments related to actual products, some research on touch expands the use of touch in marketing. Peck and Wiggins (2006) examined touch completely unrelated to a product but in the context of a persuasive ad. They varied the valence of a touch element attached to a pamphlet (negative, neutral, and positive) as well as fit of the touch element with the ad. They found that adding a touch element that felt good, for example a feather on a pamphlet requesting donations to a local arboretum, increased persuasion measured as attitude toward the ad as well as the likelihood of donating time and/or money to the organization. An unexpected finding was that the fit of the touch element with the ad did not matter for those high in autotelic NFT. Any touch element was better than no touch element for the high autotelic NFT participants. However for people low in autotelic NFT, it was important that the touch element fit with the message or it had no influence on persuasion.

In another study, not related to product touch, Hornik (1992) examined touch as non-verbal communication in an interpersonal touch context. He found, in three field settings (Study 1, a bookstore; Study 2, a restaurant; Study 3, a supermarket) that an unobtrusive touch by an employee on the arm of a customer enhanced the positive feeling for the external stimuli (e.g., the bookstore) as well as the touching source (the employee). Customers touched by a requester tended to comply more than those customers that were not touched.

Peck and Childers (forthcoming) manipulated the environment in a study in a grocery store examining impulse purchase behavior and environmental stimuli encouraging touch. They varied point of purchase signs (either no sign or "feel the freshness" encouraging touch) and

found that the sign encouraging touch resulted in more unplanned purchasing than the no sign condition. In addition, there was a main effect of the individual difference in autotelic NFT. Individuals high in autotelic NFT made more unplanned purchases than low autotelic NFT individuals.

Finally, Krishna (2006) investigated the elongation bias and shows that sensory modality (touch or vision) affects the extent and the direction of the elongation bias. The elongation bias predicts that with two containers of equal volume, the taller of the two is judged to have a larger volume. The author hypothesized that in a visual perception task, height is the salient dimension, thus the taller container appears larger. However, in another condition, when the participants had only haptic cues (they handled the objects blindfolded), width became the salient dimension and there was a reversal in the elongation bias (wide containers appeared bigger).

SUMMARY OF STUDIES

Research in the areas of olfactory, auditory, gustatory, and tactile senses can be grouped for the purposes of further discussion by whether the focus is on individual consumer factors, product or features of the stimuli, or on factors in the environment.

Individual Factors

Some research has looked at individual sensitivity to sensory input. In the area of haptics or touch research, researchers have delineated an individual difference in consumers' motivation to touch. Scales have been developed to measure this difference (Citrin et al., 2003, Peck & Childers, 2003b) and this individual difference has been found to have numerous effects. Consumers higher in their preference to touch have touch information more accessible in memory (Peck & Childers, 2003b), are not as likely to shop where they can't touch, such as on-line (Citrin et al., 2003, Peck & Childers, 2003b), are more difficult to compensate for an inability to touch (McCabe & Nowlis, 2003; Peck & Childers, 2003a), and are more likely to make impulse purchase decisions (Peck & Childers, 2003b; Peck & Childers, 2006).

In other areas of sensory research, an individual difference in the preference for information has not been as prevalent. In gustatory or taste research, taste discrimination has been an area of interest (Buchanan et al., 1987; Morrison, 1981; Moskowitz et al., 1980) and some individuals are better at discriminating various tastes compared to others. In fact, in the research on product reformulations, the goal may be to ensure that even the most taste sensitive individuals will not notice the taste change in a reformulation (Dubow & Childs, 1998). Individual differences in behavior have been the focus of some work in the taste area. In-store sampling was the context for the observation of obese and nonobese shoppers (Steinberg & Yalch, 1978) as well as consumer behavior around bulk food bins (Johnson, Sommer, & Martino, 1985). In some taste research, differential results have been found for different levels of users and non users of brands (Maison, Greenwald, & Bruin., 2004) and researchers have called for a consideration of this individual difference in research (Villani & Morrison, 1976).

Similarly, a call has been made in the area of music to consider individual listener characteristics in response to different types of music (Bruner, 1990, Kellaris & Kent, 1994). Individual differences have been manipulated by manipulating involvement (MacInnis & Park, 1991; Park & Young, 1986) but, in general, individual responses to music or other auditory stimuli have not been examined in marketing.

Product or Stimuli Factors

Besides individual factors, some research focuses on the differences in products or stimuli and sensory research. Using real products versus pictures or sketches can produce differential product evaluations (Holbrook, 1983). This is at least partially due to information that is available through direct product experience versus another medium such as advertising (Smith & Swinyard, 1983). Both touch and taste are more directly related to specific products as compared to scent and music which may be ambient and may or may not be associated with a specific product. It can be argued that when judging physical products, touch and taste may give relatively more information about products when touch or taste is available compared to when it is not.

The sense of touch has been found to matter more for different types of product categories, those that vary on product attributes best determined by touch such as texture or weight (McCabe & Nowlis, 2003, Peck & Childers, 2003a). Tasting in the context of in-store sampling seems to be more critical for store versus national brands (Bellizzi & Martin, 1982; Sprott & Shrimp, 2004) presumably because in these instances of touch and taste, sensory experience is diagnostic with respect to product quality. Yet, taste may be overridden by inferences regarding packaging (McDaniel & Baker, 1977) or brand name (LeClerc, Schmitt, & Dubé, 1994). Although it may be assumed that there is no substitute for direct product experience through taste or touch, the framing of the experience can influence customer perceptions (Levin & Gaeth, 1988). In fact, the memory of the actual experience can be altered through post experience advertising (Braun, 1999).

Products have also been examined in terms of familiarity of brands and sensory influences. An ambient scent had more impact on less familiar brands (Morrin & Ratneshwar, 2000; Spangenberg, Crowley, & Henderson, 1996), thereby providing an outcome similar to the research on taste influencing store or generic brands more than national brands (Bellizzi & Martin, 1982; Sprott & Shrimp, 2004). However, Morrin and Ratneshwar (2003), in a follow up study, found that ambient scent improved recall and recognition of both familiar and unfamiliar brands through an increase in attention.

In examining the product/stimuli factors, the idea of fit or congruence is a common theme. In general, the notion of fit has to do with a consumer's perception of the relevance of two elements. Whether the product class was congruent with the sensory element didn't matter as far as recall or recognition of brand names (Morrin & Ratneshwar, 2000, 2003), yet congruency encouraged more thorough decision making (Mitchell et al., 1995). In a background music study, Schlosser (1998) found that only social identity and not utilitarian product evaluations were influenced by retail atmospherics. Here, music was only one element of the retail atmosphere that fit with the other elements to convey either a prestige or a discount environment. Whether a sensory element fit with an advertisement has been manipulated with music (Kellaris, Cox, & Cox, 1993; McInnis & Park, 1991) and touch (Peck & Wiggins, forthcoming). Fit of the affective tone of an ad (Gorn et al., 2001) and purchase occasion (Alpert et al., 2005) with a person's mood evoked by music has also been examined. In general, a fit tends to facilitate processing.

Environmental Factors

While individual and product differences have been studied in consumer behavior, the majority of research involves manipulating elements of the environment to determine various consumer processing and behavior effects. Since scent and music are often ambient, it follows that an environmental manipulation is logical. Much of the research in scent and music falls into the retail atmospherics category and will be discussed first. Environmental factors associated with taste con-

cern the opportunity to taste and in-store sampling. Similarly, the opportunity to touch has been manipulated, sometimes in the context of online versus in-store shopping environments. Finally, notions of fit or congruency of the environment and various sensory elements will be discussed.

In-store environments have been altered by sensory elements. Perceptions of the retail environment have been found to be influenced by scent (Chebat & Michon, 2003) and music (Dubé & Morin, 2001), which ultimately influenced the positive affect of the shopper. Sensory elements have been manipulated along with social cues and the density of the retail environment (scent, Michon et al., 2005) and the number of visible employees and customers (music, Baker et al., 1992). Music has also been shown to influence mood, which influences product choice (Gorn, 1982), especially when a shopper is not aware of the source of their mood (Gorn et al., 1993).

An active area of research concerns sensory stimuli in retail environments and actual time shopping or waiting as well as time perceptions (Antonides et al., 2002; Cameron et al., 2003; Hui et al., 1997; Kellaris & Kent, 1992, Milliman, 1982, 1986; Spangenberg et al., 1996; Yalch & Spangenberg, 2000). Research has examined actual time in an establishment (e.g., Milliman 1982 (music tempo), Spangenberg et al., 1996 (scent)) as well as perceived time (e.g., Yalch & Spangenberg, 2000). It is clear that sensory elements in the environment can alter time perceptions. For example, a positive scent (Spangenberg et al., 1996) and familiar music (Yalch & Spangenberg, 2000) resulted in shoppers thinking they had spent more time in the store than they actually did.

Similarly, pleasant music has shown to result in longer perceived wait times (Antonides et al., 2002; Hui et al., 1997; Kellaris & Kent, 1992), but a more positive evaluation of the service or retail establishment (Antonides et al., 2002; Cameron et al., 2003).

The opportunity to taste has been examined in the context of in-store sampling. The choice of a generic or store brand versus a national brand can be influenced by in-store sampling (Bellizzi & Martin, 1982; Sprott & Shrimp, 2004), but brand awareness can limit the choices sampled and the quality of the choice (Hoyer & Brown, 1990). An in-store distraction when tasting can also increase the purchase likelihood of the sampled food (Nowlis & Shiv, 2005; Shiv & Nowlis, 2004). In touch research, environmental salience of touch has been manipulated through a point of purchase sign encouraging touch (Peck & Childers, forthcoming). Increasing the environmental salience of touch increased impulse purchasing. The opportunity to touch has been manipulated, and researchers have examined types of compensation for when touch is unavailable (McCabe & Nowlis, 2003; Peck & Childers, 2003a). Hornik (1992) brings together taste and touch by examining the influence of interpersonal touch and in-store sampling (Study 3) and finds that unobtrusive interpersonal touch increased compliance behavior (larger number of people sampled).

Similar to product/stimuli factors, the notion of fit or congruency has been an active area of study. In some cases, the fit of the task to the particular sense has been examined. Krishna finds that the elongation bias is visual, and touch or haptic exploration reversed this bias. Russell (2002) noted that a congruency between type of product placement (audio or visual) and how embedded the placement is in the script differentially influenced memory and persuasion. While memory was enhanced for incongruity, persuasion was enhanced for congruency. Similarly, Unnava et al. (1996) found that a mismatch between sensory modality (audio or visual) and imagery modality increased recall for advertising information. Costley et al. (1997) investigated the nature of the modality of a retrieval cue (audio or visual) and found that recall was greatest when a modality match was present.

Other elements of fit or congruency that have been investigated concern the fit of scent and music (Mattila & Wirtz, 2001, Spangenberg et al. forthcoming), music and the retail store (Chebat et al., 2001; Grewal et al., 2003; Meyer 1981, Spangenberg et al., forthcoming), music with the

advertising message (Gorn et al., 2001; MacInnis & Park, 1991), touch and the advertising message (Peck & Wiggins, 2006), music and purchase occasion (Alpert et al., 2005), and scent and product class (Mitchell et al., 1995). In general, positive effects of congruency or fit have been found. Following this synthesis of past research studies, we next consider some significant gaps that emerge from our review and discuss their potential for future research on sensory factors on consumer behavior.

FUTURE RESEARCH

Individual Differences—Ability and Preferences

An area for future investigation concerns whether an individual difference in sensory perception is a result of a differential ability or sensitivity of individuals to different types of sensory input or more of a motivation or preference for certain types of sensory information. The ability of individuals to obtain information refers to the capability of an individuals' sensory system. In the area of taste discrimination, it appears that some individuals may have greater sensitivity to variations in taste, or a greater ability to determine differences (e.g., Buchanan et al., 1987). However, in touch research, the focus has been on the motivation or preference for touch information by different individuals (e.g., Citrin et al., 2003; Peck & Childers, 2003b). Similarly, a preference for visual versus verbal information has been documented (Heckler, Childers, & Houston, 1993). Why do some individuals prefer different types of sensory information?

A logical step in sensory research would be to identify whether sensitivity to one type of sensory input translates to other types of sensory information. For example, women have been found to be more affected by scent (Bone & Ellen, 1999), music (Grewal et al., 2003), and touch (Citrin et al., 2003) compared to men. Do the individuals with a preference for a type of sensory information also have a greater ability or sensitivity to that type of information? Are people that are motivated to obtain one type of sensory input generally motivated to explore with their other senses as well? Perhaps taste and touch, being more direct senses are related more than smell and hearing. There are all unanswered questions in our literature.

Multi-Sensory Integration

Another major area in need of future research is the need to move from a more "sense by sense" perspective to investigations of the multi-sensory integration of sensory inputs. As Calvert, Spence, and Stein (2004, p. xi) note, "There can be no doubt that our senses are designed to function in *concert* and that our brains are organized to use the information they derive from their various sensory channels *cooperatively* in order to enhance the probability that objects and event will be detected rapidly, identified correctly, and responded to appropriately" (emphasis added). Ernst, Bulthoff, and Newell (2003; cited in Newell 2004) found that bimodal recognition was enhanced by 10% versus learning that occurred either visually or haptically. Recent research has examined how such cross modal interactions can affect the processing of texture perception (Lederman & Klatzky, 2004), recognition (Newell, 2004), as well as selective attention (Marks, 2004). For instance, Marks (2004) reviews studies on congruence across vision, audition, and tactile inputs. He distinguishes between cross modal interactions that facilitate versus interfere with judgments that can be differentiated by their perceptual (more semantic) versus stimulus similarities. Soto-Faraco, Lyons, Gazzaniga, Spence, and Kingstone (2002) found strong congruence effects for vision and hearing when the stimuli co-occurred temporally and spatially. One implication is that perceptual congruence rests on multi-sensory relativity within context, whereas stimulus congruence is more likely to be driven

by the absolute values of the stimulus features. This research might bear additional insight on the perceptual versus conceptual effects of fluency on, for example, logos (Janiszewski & Meyvis, 2001). Likewise, Lederman and Klatzk (2004) conclude there is no sensory dominance of texture by vision and haptics, but rather processing is driven by the contextual emphasis of an object's surface (e.g., roughness or spatial density). These authors propose the modality appropriateness hypothesis, which focuses on the weights given sensory stimuli under unimodal performance when predicting the effects for multi-sensory integration judgments.

Multi-Sensory Mental Imagery

Mental imagery is a mental representation of something (esp. a visible object), not by direct perception, but by memory representation, i.e., a mental picture or impression, an idea, or conception (Richardson, 1999). This definition, like the work in consumer behavior, places much emphasis on visual mental imagery. However, imagery may be elicited by all of the senses and the papers reviewed in this chapter are conspicuous in the lack of attention directed toward gustatory, auditory, olfactory, and tactile imagery. How these images might affect consumer processing need to be investigated from both an individual differences perspective as well as how these forms of imagery would mediate the kinds of stimulus congruency, memory, attitude, and judgment effects summarized in this review. Some research suggests that tactile discrimination is mediated by visual imagery (Sathian, Zangaladze, Hoffman, & Grafton, 1997). Grunwald, Weiss, Krauss, Beyer, Rost, and Gutbertlet (2001) also report the involvement of visual areas of the brain in haptic object recognition and suggest a spatially-based integration of information (also see Kosslyn, Pascual-Leone, Felician, Camposano, Keenan, & Thompson, 1999). In her review, Newell (2004) concludes that visual imagery mediates, and is perhaps necessary, for tactile tasks, but given findings on cross modal facilitation it may be that other imaginal modalities may play a role as well. For instance, how might olfactory imagery affect gustatory cues in flavor perception (Dalton, Doolittle, Nagata, & Breslin, 2000).

Brain Imaging Techniques and Sensory Factors

Investigation of these effects across modalities also raises an opportunity for research in consumer behavior using alternative methodologies. Yoon, Gutchess, Feinberg, and Polk (forthcoming) used functional magnetic resonance imaging (fMRI) to investigate whether judgments about products and persons share similar neural correlates. Their results show that human descriptor judgments are processed in the medial prefrontal cortex, whereas judgments about products occurred in the left inferior prefrontal cortex. The use of a variety of human imaging techniques, including EEG, MEG, PET, as well as fMRI, represent a significant challenge to researchers trained in more behaviorally based experimental paradigms, but the multi-sensory nature of consumption experiences represents a rich context for the application of these techniques. Using fMRI, Grill-Spector, Kushnir, Edelman, Itzhak, and Makach (1998) found that the lateral occipital complex (occipitotemporal areas) responds to visual objects defined by motion or texture. Amedi, Malach, Hendler, Peled, and Zohary (2001) also report activity in the same visual area for haptic based object identification. These results are also consistent with fMRI results reported by James, Humphrey, Gati, Servos, Menon, and Goodale (2002) for haptic priming on visual object recognition. One application of these techniques would be to support the validation efforts of psychometric assessments of new measures of individual difference scales, particularly in the area of multi-sen-

sory imagery. Another would be a deeper understanding of how different specialty populations process sensory factors.

Sensory Interactions with Specialty Populations

To date, only a limited amount of consumer research has examined how disabled consumers fare in their consumption environment (cf., Kaufman-Scarborough, 1999). However, considerable research on brain plasticity (how neighboring cortical areas can remap as a result of sensory deprivation) suggests this population offers much potential for a deeper understanding of how sensory information is processed, stored, and utilized (for an indepth discussion, see sections VI and VII in Calvert, Spence, & Stein, 2004). Sadato, Pascual-Leone, Grafman, Ibanez, and Dold (1996) using PET found activation in primary visual areas of the brain in visually impaired individuals while reading Braille letters. However, no similar pattern of activation was found for sighted participants (see also, Kujala, Huotilainen, Sinkkonen, Ahonen, Alho, & Hamalainen, 1995) for auditory stimulation of the visual cortex). Similarly, visual stimulation has also increased activation of the auditory primary cortex for deaf, but not hearing-abled individuals (Finney, Fine, & Dobkins, 2001). These results raise interesting questions of how the visually impaired shop online using audio-based screen readers and how the addition of tactile-based graphics might affect their purchasing versus their sighted counterparts. Also, what effect would visual imagery instructions have on online visually impaired shoppers? Would resource consuming imagery overload these consumers as they are externally paced through a Web page through this assistive technology?

In addition to disabled consumers, sensitivity to sensory inputs likely varies by age. While one study with children has looked at the processing of audio and visual information (Macklin, 1994), it is clear that much more research could be done. The aging population also has implications for sensory exploration. In general, sensitivity to stimuli declines with age (c.f. touch, Thornbuy & Mistretta, 1981; Stevens & Patterson, 1995) so that it may take an increase in intensity of sensory stimuli to be perceived by older populations. For example, ambient scent may need to be more concentrated, and music may need to be louder. Beside a differential ability in perception, preferences are likely to differ by age, at least for some sensory stimuli, such as music.

Conscious Versus Nonconscious Sensory Processing

“When he (Freud) said that consciousness is the tip of the mental iceberg, he was short of the mark by quite a bit—it may be more the size of a snowball on top of that iceberg” (Wilson, 2002, p. 6). Does the individual have to be conscious of the sensory input in order for it to be influential? There seems to be some evidence that awareness may not be critical. Although not the focus of the studies, research in both scent (Hirsch, 1995; Morrin & Ratneshwar, 2000) and music (Milliman, 1982) has found that consumers may not even be aware of these environmental stimuli. Holland, Hendriks, and Aarts (2005) found that when individuals were exposed to citrus-scented cleaner, the accessibility of cleaning was increased (Studies 1 and 2) and cleaning behavior increased (Study 3). In addition, subjects were unaware of the influence of scent on both their memory accessibility and their behavior. The nonconscious processing of sensory information may be more likely for sensory stimuli present in the environment in which the consumer is passively surrounded with the sensory information (i.e., olfactory and auditory) compared to when direct physical contact is necessary for sensory input (i.e., gustatory and haptic). Given the rise in interest and knowledge of nonconscious processing and some evidence that individuals can be influenced without their awareness in various sensory domains, this area is worthy of further study.

In Conclusion, to Make a Full Turn: If It Tastes, Smells, Sounds, and Feels Like a Duck, Then It Must Be a ... (Duck)

“Perhaps,” would seem to be the best answer. Sensory stimuli can aid in our processing of information and sometimes can bias and mislead us in forming our impressions. This fascinating contradiction, however, makes the study of sensory factors in consumer behavior challenging and all the more rewarding as we further our investigations of how consumers make sense of their world.

Stages of Consumer Socialization

The Development of Consumer Knowledge, Skills, and Values From Childhood to Adolescence

DEBORAH ROEDDER JOHN

University of Minnesota

Scholarly research examining children's consumer behavior dates back to the 1950s with a few publications on topics such as brand loyalty (Guest, 1955) and conspicuous consumption (Reisman & Roseborough, 1955). Further development took place in the 1960s, as the scope of inquiry expanded to include children's understanding of marketing and retail functions (McNeal, 1964), influence on parents in purchasing decisions (Berey & Pollay, 1968; Wells & LoSciuto, 1966), and relative influence of parents and peers on consumption patterns (Cateora, 1963). Interest in the topic exploded in the mid 1970s amidst vocal criticisms of advertising to young children, mounted by consumer activist groups such as Action for Children's Television (ACT) and government bodies such as the Federal Trade Commission. Emerging from this growing interest was a new field of academic study—consumer socialization—focusing on the acquisition of skills, knowledge, and values by children and adolescents as they prepared to take their role as consumers in the marketplace.

Thirty years later, an impressive body of research on children's consumer socialization has emerged. Researchers have explored a wide range of topics, including learning about products, brands, advertising, shopping, pricing, decision-making strategies, parental influence approaches, and consumption motives and values. Advertising effects have also been a popular topic, ranging from a large number of studies examining features of children's advertising that are more persuasive to a smaller number of studies examining the cumulative effective of advertising on children's values and consumption patterns. The undesirable consequences of marketing and advertising—such as underage drinking, cigarette smoking, and unhealthy diets—have also received attention throughout the years.

The purpose of this chapter is to merge findings from the last thirty years of research into a unified story of how consumer socialization occurs from childhood to adolescence. To provide an organizing theme, we focus on age-related developments in consumer socialization, with the objective of characterizing what children know and how they think as consumers at different ages. We acknowledge that important developments in consumer socialization take place in a social context, including family, peers, mass media, and marketing institutions. But, in order to provide the fullest picture of consumer socialization at different ages, we focus on age-related developments as the basis for our conceptualization.

We include research published in consumer behavior and marketing journals from 1975 to 2005. Findings reported earlier than 1975, or reported in journals outside consumer research, are included only to provide context or corroboration for more recent work by consumer researchers. Excluded from our discussion is research pertaining to children's consumption of products such as cigarettes, alcohol, and illegal drugs, which constitutes a vast body of literature reviewed elsewhere (for reviews, see U.S. Department of Health and Human Services, 1994, 1995). Also excluded is consumer research pertaining to children but outside the realm of consumer socialization, such as: (1) studies of the effects of advertising strategies, such as host selling or repetition, on children's responses to advertising; (2) content analyses of television commercials aimed at children; (3) surveys about parental views of advertising and marketing to children; and (4) discussions of specific public policy issues and regulatory debates (for reviews of these areas, see Adler et al., 1980; Young, 1990).

This chapter is divided into three parts. First, we provide a conceptual overview of consumer socialization, summarizing important theoretical views on cognitive and social development and developing a conceptual framework that describes stages of consumer socialization. These stage descriptions identify general characteristics of children's knowledge, skills, and reasoning at different ages. In the second part, we review research pertaining to the three stages of consumer socialization—perceptual, analytical, and reflective stage. Reviewed are findings about children's knowledge of advertising, products and brands, shopping, pricing, decision making, purchase influence strategies, and consumption motives and values. We conclude with a discussion of the challenges for future research addressing stages of consumer socialization.

STAGES OF CONSUMER SOCIALIZATION

Consumer socialization occurs in the context of dramatic cognitive and social developments, which take place from birth to adolescence. A common approach is to characterize these developments as a series of successive stages, with each stage describing children's thought, reasoning, and perspectives at particular ages. Below, we describe several frameworks most relevant for our subsequent discussion of consumer socialization.

Stages of Cognitive and Social Development

Cognitive Development. The most well known framework for characterizing developments in cognitive abilities is Piaget's theory, which proposes four main stages of cognitive development: sensorimotor (birth to 2 years), preoperational (2 to 7 years), concrete operational (7 to 11 years), and formal operational (11 through adulthood) (Ginsburg & Opper, 1988). Vast differences exist in the cognitive abilities of children at these stages, including the preoperational, concrete operational, and formal operational stages of most interest to consumer researchers. Preoperational children tend to be "perceptually-bound" to the readily-observable aspects of their environment, unlike concrete operational children, who do not accept perception as reality but can think about stimuli in their environment in a more thoughtful way. Preoperational children are also characterized by "centration," the tendency to focus on a single dimension. In contrast, the concrete operational child can consider several dimensions of a stimulus at a time and relate the dimensions in a thoughtful and relatively abstract way. Finally, in the formal operational stage, children progress to more adult-like thought patterns, capable of even more complex thought about concrete and hypothetical objects and situations.

Information processing theories of child development provide additional explanatory power for the types of cognitive abilities evidenced by children as they mature. Several formulations of information processing theory exist, but all share a focus on children's developing skills in the areas of acquisition, encoding, organization, and retrieval of information. In the consumer behavior literature, children have been characterized as belonging to one of three segments—strategic processors, cued processors, and limited processors—based on information processing skills they possess (Roedder, 1981). Strategic processors (age 12 and older) use a variety of strategies for storing and retrieving information, such as verbal labeling, rehearsal, and use of retrieval cues to guide memory search. Cued processors, ranging in age from 7 to 11 years, are able to use a similar set of strategies to enhance information storage and retrieval, but typically need to be aided by explicit prompts or cues. Finally, most children under the age of 7 years are limited processors, with processing skills that are not yet fully developed nor successfully utilized in learning situations, even when prompted to do so.

Social Development. The area of social development includes a wide variety of topics, such as moral development, altruism and pro-social development, impression formation, and social perspective taking. In terms of explaining aspects of consumer socialization, we consider social perspective taking and impression formation to be the most directly relevant for our consideration. Social perspective taking, involving the ability to see perspectives beyond one's own, is strongly related to purchase influence and negotiation skills. Impression formation, involving the ability to make social comparisons, is strongly related to understanding the social aspects of products and consumption.

Developments in social perspective taking are described well by Selman (1980). In the preschool and kindergarten years, the egocentric stage (ages 3–6), children are unaware of any perspective other than their own. As they enter the next phase, the social informational role taking stage (ages 6–8), children become aware that others may have different opinions or motives, but believe this is due to having different information rather than a different perspective on the situation. Thus, children in this stage do not exhibit the ability to actually think from another person's perspective. This ability surfaces in the self-reflective role taking stage (ages 8–10) as children understand that others may have different opinions, even if they have the same information. They can consider another person's viewpoint, but not simultaneously with their own, an ability that does not emerge until the fourth stage of mutual role taking (ages 10–12). This is a most important juncture as much social interaction, such as persuasion and negotiation, requires dual consideration of both parties' perspectives. The final stage, social and conventional system role taking (ages 12–15 and older), features an additional development, the ability to understand another person's perspective as it relates to the social group to which he (other person) belongs or the social system in which he (other person) operates.

Impression formation abilities also undergo dramatic development, as described by Barenboim (1981). Before the age of six, children describe other people in concrete or absolute terms, often mentioning physical appearances ("Nick is tall") or overt behaviors ("Elizabeth likes to skate"). However, these descriptions do not incorporate comparisons with other people. In Barenboim's first stage, the behavioral comparisons phase (ages 6–8), children do incorporate comparisons as a basis of their impressions, but the comparisons continue to be based on concrete attributes or behaviors ("Matthew runs faster than Sam"). In the second stage, which Barenboim calls the psychological constructs phase (ages 8–10), impressions are based on psychological or abstract attributes ("Rosemary is friendly"), but do include comparisons to others. Comparisons based on

psychological or abstract attributes do not emerge until the psychological comparisons phase (11 or 12 years of age and older), which features more adult-like impressions of people (“Sara is more outgoing than Amy”).

Stages of Consumer Socialization

We propose that consumer socialization be viewed as a developmental process occurring in a series of stages as children become socialized into their roles as consumers. Changes occur as children move through three stages of consumer socialization—the perceptual stage (ages 3–7), the analytical stage (ages 7–11), and the reflective stage (age 11–adult). The perceptual stage derives its name from the overwhelming emphasis that children in this stage place on perceptual as opposed to abstract or symbolic thought. The analytical stage is named for the vast improvements we see at this stage in children’s abilities to approach matters in more detailed and analytical ways. Finally, the reflective stage derives its name from the ability of children of this age to reflect on the complex social contexts and meanings related to consumption. These stages are characterized along a number of dimensions that capture important shifts in knowledge development, decision-making skills, and influence strategies, as described below (see Table 8.1).

Perceptual Stage. The perceptual stage (ages 3–7) is characterized by a general orientation toward the immediate and readily observable perceptual features of the marketplace. Piaget’s notion of “perceptual boundness” describes these children well, as does his idea of “centration” on single dimensions of objects and events. Children’s consumer knowledge is based on perceptual features

Table 8.1 Consumer Socialization Stages

Characteristics	Perceptual stage, 3–7 years	Analytical stage, 7–11 years	Reflective stage, 11–16 years
Knowledge structures:			
Orientation	Concrete	Abstract	Abstract
Focus	Perceptual features	Functional/underlying features	Functional/underlying features
Complexity	Unidimensional Simple	Two or more dimensions Contingent (“if-then”)	Multidimensional Contingent (“if-then”)
Perspective	Egocentric (own perspective)	Dual perspectives (own + others)	Dual perspectives in social context
Decision-making and influence strategies:			
Orientation	Expedient	Thoughtful	Strategic
Focus	Perceptual features Salient features	Functional/underlying features Relevant features	Functional/underlying features Relevant features
Complexity	Single attributes Limited repertoire of strategies	Two or more attributes Expanded repertoire of strategies	Multiple attributes Complete repertoire of strategies
Adaptivity	Emerging	Moderate	Fully developed
Perspective	Egocentric	Dual perspectives	Dual perspectives in social context

and distinctions, often based on a single dimension or attribute, and represented in terms of concrete details from their own observations. These children exhibit familiarity with concepts in the marketplace, such as brands or retail stores, but rarely understand them beyond a surface level. Due to constraints in encoding and organizing information, individual objects or experiences are rarely integrated into more generalized knowledge structures with multiple dimensions, perspectives, and contingencies (“if-then” rules).

Many of these same characteristics hold true for consumer decision-making skills and influence strategies at the perceptual stage. The orientation here can best be described as simple, expedient, and egocentric. Decisions are often made on the basis of very limited information, often on the basis of a single attribute that is perceptually salient (e.g., size). This strategy is rarely modified to fit different choice tasks or situations. Limited adaptivity is also a feature of children’s influence strategies. Children approach these situations from an egocentric perspective, unable to incorporate another person’s perspective in using a strategy to influence or negotiate for desired items. Although they may be aware that parents have other views, children at this age have difficulty thinking about their own perspective and that of other person simultaneously.

Analytical Stage. Enormous changes take place, both cognitively and socially, as children move into the analytical stage (ages 7–11). This period contains some of the most important developments in terms of consumer knowledge, skills, and consumption motivations. The shift from perceptual thought to more symbolic thought noted by Piaget, along with dramatic increases in information processing abilities, results in a more sophisticated understanding of the marketplace, a more complex set of knowledge about concepts such as advertising and brands, and a new perspective that goes beyond their own feelings and motives. Concepts such as product categories or prices are thought of in terms of functional or underlying dimensions, products and brands are analyzed and discriminated on the basis of more than one dimension or attribute, and generalizations are drawn from one’s experiences. Reasoning proceeds at a more abstract level, setting the stage for knowledge structures that include information about abstract concepts such as advertiser’s motives as well as the notion of contingencies (e.g., sweetness is an appealing attribute for candy but not soup).

The ability to analyze stimuli on multiple dimensions and the acknowledgement of contingencies brings about vast changes in children’s consumer decision-making skills and strategies. Now, children exhibit more thoughtfulness in their choices, considering more than just a single perceptually salient attribute and employing a decision strategy that makes sense given the task environment. As a result, children are more flexible in the approach they bring to making decisions, allowing them to be more adaptive. These tendencies also emerge in the way children try to influence and negotiate for desired items. The approach is more strategic, based on their newfound ability to think from the perspective of a parent or friend and adapt their influence strategy accordingly.

Reflective Stage. The reflective stage (ages 11–16) is characterized by further development in several dimensions of cognitive and social development. Knowledge about marketplace concepts such as branding and pricing becomes more mature and complex as children develop more sophisticated cognitive and social skills. Many of these changes are more a matter of degree than kind. More distinct is the shift in orientation to a more reflective way of thinking and reasoning, as children move into adolescence and become more focused on the social meanings and underpinnings of the consumer marketplace. A heightened awareness of other people’s perspectives, along with a need to shape their own identity and conform to group expectations, results in more attention to the social aspects of being a consumer, making choices, and consuming brands. Consumer decisions are made in a more adaptive manner, depending on the situation and task. In a similar fashion, attempts to influence parents and friends reflect more social awareness as adolescents become more strategic, favoring strategies that they think will be better received than a simple direct approach.

Discussion. The consumer socialization stages being proposed here capture important changes in how children think, what they know, and how they express themselves as consumers. These stage descriptions, similar to other stage frameworks found in child psychology, have tremendous heuristic value. Yet, it is important to keep several caveats in mind. First, the ages associated with each stage are approximations based on the general tendencies of children in that age group. To constrain the number of stages to a reasonable number, some degree of variance among children in an age range was tolerated. For example, children 7 to 11 years of age are identified with the analytical stage, even though differences in degree clearly exist at the extremes. To deal with variations of this sort, we formulated our stage descriptions to be most representative of children in the middle to end of each age range and allowed the age ranges to overlap at transition points between stages. Second, we note that the nature of the task environment or marketing stimuli can alter the age at which certain knowledge or behaviors would occur. Tasks that are more complex, requiring consideration of more information or more in-depth knowledge, can be expected to increase the age at which children appear to have mastered a particular concept.

We turn now to a review of empirical findings pertaining to stages of consumer socialization. We begin our discussion by examining evidence about children's consumer knowledge, skills, and motivation for the first stage of consumer socialization—the perceptual stage.

PERCEPTUAL STAGE

Advertising and Persuasion Knowledge

Much of the concern about television advertising to children has been focused on children under the age of eight, who have been found to have a limited understanding of advertising. One of the few skills that emerge during this stage is the ability to identify television commercials and distinguish them from other forms of programming. By age five, almost all children have acquired the ability to pick out commercials from regular television programming (Blosser & Roberts, 1985; Butter, Popovich, Stackhouse, & Garner, 1981; Levin, Petros, & Petrella, 1982; Mallalieu, Palan, & Laczniak, 2005; Palmer & McDowell, 1979; Stephens & Stutts, 1982; Stutts, Vance, & Hudleson, 1981). Even 3- and 5-year-olds have been shown to discriminate commercials above chance levels (Butter, et al., 1981; Levin et al., 1982).

However, the ability to identify commercials does not necessarily translate into an understanding of the “true” difference between commercials and programs (entertainment vs. selling intent). Children under the age of six or seven usually describe the difference between commercials and programs using simple perceptual cues, such as “commercials are short” (Butter et al., 1981; Palmer & McDowell, 1979; Ward, 1972). Young children often view advertising as entertainment (e.g., “commercials are funny”) or as a form of unbiased information (e.g., “commercials tell you about things you can buy”). Although preschool children may implicitly understand that commercials include mainly positive statements about advertised products (Pine & Veasey, 2003), explicit understanding of the selling intent of advertising does not emerge until many children are seven or eight years of age (Macklin, 1985; Ward, Wackman, & Wartella, 1977). For example, in a landmark study with first graders (6 to 7-year-olds), only 50% described the purpose of commercials as trying to sell something (Robertson & Rossiter, 1974).

Product and Brand Knowledge

In addition to advertising, products and brands are the most salient aspects of the marketplace for young consumers. Products and brands are advertised on television, displayed in stores, and

found in the home. Even before they are able to read, children as young as two or three years of age can recognize familiar packages in the store and familiar characters on products such as toys and clothing (Derscheid, Kwon, & Fang, 1996; Haynes, Burts, Dukes, & Cloud, 1993). By preschool, children begin to recall brand names from seeing them advertised on television or featured on product packages, especially if the brand names are associated with salient visual cues such as colors, pictures, or cartoon characters (Macklin, 1996). By the time children reach first grade, most can recall at least one brand in popular child-oriented product categories, such as candy and fast food (Ward et al., 1977).

During this time, children develop a preference for particular brands. Children begin to express a preference for familiar branded items over generic offerings in the preschool years (Hite & Hite, 1995), with preference for branded items escalating further as children enter elementary school (Ward et al., 1977). In a clever study analyzing children's letters to Santa, Otnes, Kim, and Kim (1994) found that about 50% of children's gift requests were for specific branded (toy and game) items, with the vast majority of children (85%) mentioning at least one brand name in their letter to Santa.

Despite these developments, children's understanding of products and brands is limited by a focus on perceptual attributes that are visually dominant, such as shape, size, or color. Product categorization is a vivid illustration of this point. Although children learn to group or categorize products at an early age, young children rely on highly visible perceptual attributes to categorize products and discriminate brands (John & Lakshmi-Ratan, 1992; Klees, Olson, & Wilson, 1988). For example, in a study by John and Sujun (1990), preschoolers (ages 4–5) grouped beverage products together based on having similar packaging (e.g., cans vs. bottles), label colors (e.g., green vs. red), and size (e.g., 2-liter vs. 16 oz. bottles). Older children (ages 9–10) placed more emphasis on underlying attributes such as taste (e.g., cola vs. lemon-lime) or carbonation (e.g., orange juice vs. soft drink).

Shopping Knowledge and Skills

A major accomplishment at this stage is an understanding of money as a medium of exchange. Early childhood is a period of rapid development in abilities to understand where money comes from, to identify specific coins and bill values, and to carry out transactions with money involving simple addition and subtraction (Marshall, 1964; Marshall & MacGruder, 1960; Strauss, 1952). Significant jumps in knowledge occur between preschool and first and second grade, with most second graders having acquired many of the basic concepts for understanding the exchange of money for goods and services.

Also developing is an understanding of the basic sequence of events involved in the shopping process. Children acquire a vast amount of experience as an observer of the shopping process at very early ages, but these experiences do not result in an understanding of the basic shopping script until children reach the preschool or kindergarten years (Berti & Bombi, 1988; Karsten, 1996). Karsten (1996) illustrates this point in her study with kindergartners through fourth graders, who were asked to participate in a "shopping game." Each child was shown a small toy with a price tag and was given money to buy the item at a play store. A store area was set up nearby with a small cash register, containing visible amounts of coins and bills. Children were asked to show the interviewer how they would buy the toy in the store. Even the youngest children in the study enacted the basic shopping script. Kindergartners understood that one needed to select an item, check on the money available, place it on the cashier's counter, wait for the cashier offer change, and obtain a receipt.

Decision-Making Skills and Abilities

Children assume the role of consumer decision makers at a young age. During the period from preschool to early elementary school, one of the most important skills to emerge is the ability to adjust information search according to costs and benefits of additional search. Preschoolers can adjust their information search according to *either* costs or benefits (Davidson & Hudson, 1988, experiment 1), but adjusting information search in line with *both* costs and benefits emerges later as children move into elementary school. In a study with 4- to 7-year-olds, Gregan-Paxton and John (1995) found that 6- to 7-year-olds modified their search behavior in line with appropriate cost-benefit trade-offs, gathering the least amount of information in the condition with the least favorable cost-benefit profile (high cost, low benefit) and the most information in the condition with the most favorable cost-benefit profile (low cost, high benefit). Younger children (ages 4–5) were less discerning, however, gathering the most information for one of the conditions warranting a very modest degree of search (low cost, low benefit) and much less information for one of the conditions warranting the most extensive information search (low cost, high benefit).

The type of information gathered is often perceptual in nature, whether or not it is relevant for the decision at hand (Wartella, Wackman, Ward, Shamir, & Alexander, 1979). Once information is gathered, young children do not always utilize the information in an effective manner. Kindergarten children often rely on a single attribute or dimension in forming preferences, comparing products, or choosing one alternative from a set of options (Bahn, 1986; Capon & Kuhn, 1980; Ward et al., 1977; Wartella et al., 1979). The focus on perceptual data and single attributes is the hallmark of decision making in children at the perceptual stage.

Purchase Influence and Negotiation Strategies

Children influence purchases at a very young age. At this stage, children approach influence attempts from an egocentric perspective, with the goal of getting what they want instead of persuading parents who may have a different viewpoint on the purchase. Toddlers and preschool children exert their influence in a very direct way, often pointing to products and occasionally grabbing them off store shelves for deposit inside their parent's shopping cart (Rust, 1993). As children become more verbal, they ask for products by name, sometimes begging, screaming and whining to get what they want (McNeal, 1992). For frequently-purchased items, such as snack food and cereal, children are often able to exert their influence simply by asking (Isler, Popper, & Ward, 1987), due to parents who become more accepting of children's preferences for such items and more comfortable with the idea of occasionally yielding to those preferences.

Consumption Motives and Values

Consumer socialization involves more than the acquisition of knowledge and skills related to the consumer role. It also includes the adoption of motives and values pertaining to consumption activities. Researchers have addressed these developments by focusing on the adoption of social motivations for consumption, emphasizing consumption for social expression and status, and materialistic values, emphasizing the acquisition of material goods as a means of achieving personal happiness, success, and self-fulfillment.

Research suggests that children value material goods from a very young age, sometimes favoring them above all else. Goldberg and Gorn (1978) provide an interesting illustration in a study with 4- to 5-year-old boys. Children saw an ad for a new toy ("Ruckus Raisers") and were then given a choice between two hypothetical playmates: one described as "very nice" that did not own

the new toy and one described as “not so nice” but owning the new toy. A majority of the children selected the boy with the new toy. Children also made choices from two hypothetical play situations: playing alone with the new toy or playing in a sandbox with friends (without the toy). Again, a majority of children selected the play situation with the new toy.

However, children’s desires for material goods at this stage appear to be driven by rather simple considerations, such as novelty or quantity. Baker and Gentry (1996) provide an example in their study of collecting as a hobby among first and fifth graders. Children of all ages collected similar types of items—such as sports cards, dolls, and rocks—but did so for different reasons. First graders often compared their possessions to those of others in terms of quantity. Collecting appeared to be simply a way of getting more than someone else. Among fifth graders, however, the motivations for collecting had more social connotations. Collecting was appreciated as a way of socially expressing one’s uniqueness and attaining a sense of personal achievement by having things that others do not. These findings are consistent with our descriptions of children in the perceptual stage, who value material goods on a perceptual dimension (quantity), and the analytical stage, who see things quite differently by virtue of their social comparison skills and perspective-taking abilities.

ANALYTICAL STAGE

Advertising and Persuasion Knowledge

A full understanding of advertising intent usually emerges by the time most children are 7 to 8 years old (Bever, Smith, Bengen, & Johnson, 1975; Blosser & Roberts, 1985; Lawlor & Prothero, 2003; Robertson & Rossiter, 1974; Rubin, 1974; Ward et al., 1977). Children see the persuasive intent of commercials quite clearly, coming to terms with the fact that advertisers are “trying to get people to buy something.” In a study with first, third, and fifth grade boys, Robertson and Rossiter (1974) found that the understanding of persuasive intent increased dramatically from only 52.7% of first graders (6- to 7-year-olds) to 87.1% of third graders (8- to 9-year-olds) to 99% of fifth graders (10- to 11-year-olds). This trend supports our description of children in the analytical stage, who are capable of viewing advertising from a number of perspectives, the buyer’s (assistive intent) and the advertiser’s (persuasive intent).

Children in the analytical stage also recognize the existence of bias and deception in advertising. Children aged 8 years and older no longer believe that “commercials always tell the truth” (Bever et al., 1975; Robertson & Rossiter, 1974; Ward, 1972; Ward et al., 1977), with beliefs about the truthfulness of advertising becoming even more negative as children move toward adolescence (Bever et al., 1975; Robertson & Rossiter, 1974; Rossiter & Robertson, 1976; Ward, 1972; Ward et al., 1977). For example, Ward et al. (1977) report that the percentage of kindergartners, third graders, and sixth graders believing that advertising never or only sometimes tells the truth increases from 50% to 88% to 97%, respectively. Moreover, older children also understand why commercials are sometimes untruthful, connecting lying to persuasive intent (e.g., “they want to sell products to make money, so they have to make the product look better than it is”).

Armed with an understanding of advertising’s persuasive intent and skepticism about the truthfulness of advertising claims, children over the age of eight are often viewed as having a “cognitive defense” against advertising that shields them from being unfairly persuaded. Although this scenario seems straightforward, evidence regarding the extent to which children’s general attitudes and beliefs about advertising function as cognitive defenses is quite mixed. Early survey research was successful in finding moderate links between children’s knowledge of advertising’s persuasive intent and their desire for advertised products (Robertson & Rossiter, 1974), but more recent

experimental research finds that children's cognitive defenses have little or no effect on evaluations and preferences for advertised products (Christenson, 1982; Ross et al., 1984). For example, Christenson (1982) found that an educational segment on commercials was successful in increasing the awareness of advertising's persuasive intent and decreasing the perceived truthfulness of advertising, yet had little effect on younger (first–second graders) or older (fifth–sixth graders) children's evaluations of a subsequently advertised product. More recent research has provided an answer for this puzzle, finding that children's advertising knowledge serves as a cognitive defense only when that knowledge is accessed and used during commercial viewing (Brucks, Armstrong, & Goldberg, 1988).

Product and Brand Knowledge

Brand knowledge escalates from early to middle childhood. Children's awareness and recall of brand names increases with age, from early to middle childhood (Rossiter, 1976; Rubin, 1974; Ward et al., 1977). By the time children reach middle childhood, they can name multiple brands in most child-oriented product categories such as cereal, snacks, and toys (McNeal, 1992; Otnes et al., 1994; Rossiter, 1976; Rubin, 1974; Ward et al., 1977) and can name at least one brand in more adult-oriented product categories such as cameras and gasoline (Ward et al., 1977).

Between early and middle childhood, children also learn a great deal about the underlying structure of product categories. Children shift from using highly visible perceptual cues to more important underlying cues as a basis for categorizing and judging similarity among products (John & Sujana, 1990; John & Lakshmi-Ratan, 1992; Klees et al., 1988). By third or fourth grade, children are learning to group objects according to taxonomic relationships (e.g., belts and socks are items of clothing), attributes that indicate the relationship of categories to one another (e.g., fruit juices and soft drinks differ on the attribute of naturalness), and attributes inherent to the core concept of categories (e.g., taste, more than color, is central to the category of soft drinks). These are termed underlying, deep structure, or functional attributes because they convey the true meaning or function a category might serve. The shift to functional or underlying categorization cues around 8 to 10 years of age is consistent with symbolic thinking that characterizes children in the analytical stage.

Early to middle childhood is also a time of greater understanding of the symbolic meanings and status accorded to products. Nowhere is children's increasing understanding of the social significance of goods more in evidence than in studies of consumption symbolism (Belk, Bahn, & Mayer, 1982; Belk, Mayer, & Driscoll, 1984; Mayer & Belk, 1982). To illustrate, in the Belk et al. (1982) study, children in preschool through elementary school were shown pairs of pictures of automobiles or houses, which varied in size, age, or market value. For example, one pair included a Caprice (a large, traditional car) and a Chevette (a small economy car). Subjects were asked to pick the car that would be owned by different types of people (e.g., a doctor, a grandfather). Responses revealed that inferences based on ownership were minimal among preschoolers, emerging and evident in second graders, and almost fully developed in sixth graders. Thus, sometime between preschool and second grade, children begin to make inferences about people based on products they use (Belk et al., 1982; Mayer & Belk, 1982).

Shopping Knowledge and Skills

As children move into the analytical stage, they begin to understand more about the purpose and nature of retail establishments. The changes parallel those seen with understanding the purpose of advertising. At age 5, stores are seen as source for snacks or sweets, but children are unsure of why

stores exist except to fulfill their own needs and wants. At age 9, however, there is an understanding that retail stores are owned by people selling goods at a profit. Thus, there is a considerable shift in understanding the purpose of retail establishments from the preschool years (an egocentric view of stores as fulfilling my wants) to the early elementary school years (a dual view of stores as profit centers that fulfill consumer wants) (McNeal, 1964). This shift is consistent with our description of children in the perceptual stage, where children have an egocentric perspective, versus those in the analytical stage, where children can take another person's perspective, such as retailers who have a profit motive.

Shopping scripts also undergo development as children gain more shopping experience and transform these experiences into more sophisticated scripts. John and Whitney (1986) illustrate these developments in a study with children ages 4–5, 6–7, and 9–10 years old. Children heard different stories about a boy or girl exchanging or returning a faulty product to a store. Amount of experience was manipulated by varying the number of stories read to children, resulting in low (1 story), medium (3 stories), or high (5 stories) levels of experience. After hearing the assigned number of stories, children were asked to describe how one would go about returning or exchanging a product.

As more information became available, 9- to 10-year-olds produced scripts that were generally more abstract and complex in terms of conditional events (if “x” happens, then do “y”). For example, children picked up the differences in return and exchange policies across stories and incorporated these contingencies into their scripts. The 6- to 7-year-olds also produced more sophisticated scripts with added experience, although this effect was limited to low versus moderate levels of experience (1 vs. 3 stories). In contrast, the scripts produced by 4- to 5-year-olds were similar across experience levels, with a relatively high percentage of episodic details and no conditional events. Older children have an advantage in encoding and organizing important information about their experiences, as well as retrieving information when needed (Peracchio, 1992, 1993).

Decision-Making Skills and Abilities

Some of the most important developments in decision-making skills surface in the analytical stage. Children gather information from a variety of sources (Ward et al., 1977), focus on more relevant information and ignore irrelevant information (Davidson, 1991b; Howse, Best, & Stone, 2003; Wartella et al., 1979), consider functional/performance attributes in addition to perceptual features (Ward et al., 1977), use more attributes and dimensions in forming preferences (Bahn, 1986; Capon & Kuhn, 1980; Ward et al., 1977), and more carefully consider these preferences in making choices (Roedder, Sternthal, & Calder, 1983).

Children also begin to use a variety of compensatory and noncompensatory choice strategies (Bereby-Meyer, Assor, & Katz, 2004; Howse, Best, & Stone, 2003). Wartella et al. (1979) provide a vivid example of these developments in a study with kindergartners and third graders. Children chose a gift for a friend from a set of candies described as having different amounts of various ingredients (e.g., chocolate, raisins). To provide attribute importance information, the ingredient preferences of the gift recipient were also described (e.g., loves chocolate and hates raisins). The choice alternatives (candies) and attribute importance information was designed in such a way that the chosen gift revealed the child's choice strategy: best single attribute (candy with the highest amount of the most important ingredient), variety of attributes (candy with the highest amount of different ingredients), lexicographic strategy (candy with the highest amount of the most important ingredient and, in the case of a tie, on the highest amount of the second most important ingredient), and a weighted adding strategy (candy with the highest amounts of ingredients multiplied by importance weights for ingredients).

Kindergartners chose candies with the most ingredients, regardless of their importance to the gift recipient. However, third graders used a variety of strategies, split between the single best attribute, variety of attributes, and lexicographic strategies. The weighted adding strategy, which is compensatory in nature, was used by only a small percentage of the older children. These trends, especially the use of the single best attribute and lexicographic strategies by older children, signal the use of noncompensatory strategies in children by the time they reach middle childhood.

Purchase Influence and Negotiation Strategies

Children exert more influence as they grow older (Atkin, 1978; Darley & Lim, 1986; Jenkins, 1979; Moschis & Mitchell, 1986; Nelson, 1979; Rust, 1993; Ward & Wackman, 1972; Swinyard & Sim, 1987; Ward et al., 1977). They have the most influence over purchases of child-relevant items (e.g., cereal, toys, clothes), a moderate degree of influence for family activities (e.g., vacations, restaurants), and the least influence for purchases of consumer durables and expensive items (Belch, Belch, & Ceresino, 1985; Corfman & Harlam, 1997; Foxman & Tansuhaj, 1988; Foxman, Tansuhaj, & Ekstrom, 1989; Isler et al., 1987; Swinyard & Sim, 1987).

Influence attempts also become more sophisticated at this stage. Bargaining, compromise, and persuasion enter the picture. Instead of simple purchase requests, which are then accepted or rejected by parents, interactions between parents and children of this age feature more mutual discussion and compromise (Rust, 1993). Discussion of this sort is made possible by the fact that children are developing greater abilities to see multiple points of view, such as theirs as well as their parents, simultaneously. As we have noted, this dual perspective is characteristic of older children in the analytical stage. Children are also primed to assume a more active role in purchase discussions after years of listening to their parents describe why certain requests can or cannot be honored (Palan & Wilkes, 1997; Popper, 1979), in effect learning to reason, persuade, and negotiate for what they want. Finally, it is also the case that extended discussions become more necessary as children shift purchase requests from inexpensive items such as candy and cereal to more expensive items, including sporting goods, clothes, and electronic goods (McNeal, 1992).

Consumption Motives and Values

As children approach adolescence, they begin to understand the social meanings and status attached to possessions. As a result, social motivations for consumption emerge. In Baker and Gentry's (1996) study, described earlier, the motivations of older children (ages 10–11) for collecting items included social ones, such as expressing their uniqueness or signaling an achievement.

Materialistic values also begin to surface during this period (Achenreiner, 1997; Goldberg, Gorn, Peracchio, & Bamossy, 2003). A greater understanding of the symbolic meanings and status accorded to possessions sets the stage for desiring material goods for instrumental reasons, such as happiness or popularity. For example, Goldberg et al. (2003) found evidence of materialism in a study of 9- to 14-year-olds. Children higher in materialism exhibited behaviors we have come to expect with materialistic values, such as shopping more, saving less, and being more responsive to advertising and marketing promotions.

REFLECTIVE STAGE

Knowledge of Advertising and Persuasion

In the reflective stage, advertising knowledge develops even further, especially in terms of understanding advertiser's selling tactics. Although younger children may have a general understanding

of why commercials are sometimes untruthful, the ability to detect specific instances of bias and deception does not arrive until adolescence. For example, in a study with 7- to 12-year-olds, Bever et al. (1975) report that most of the 7- to 10-year-olds in their study could not detect misleading advertising and admitted to their difficulties: “[Advertisers] can fake well,” they said, and “you don’t really know what’s true until you’ve tried the product” (p. 114). Eleven- to twelve-year-olds were more discriminating, using nuances of voice, manner, and language to detect misleading advertising. These children used clues such as “overstatements and the way they [the actors] talk,” “when they use visual tricks or fake things,” and when the commercial “goes on and on in too much detail” (p. 119). Clearly, developments in perspective taking that occur as children enter adolescence facilitate the ability to associate such nuances in advertising executions with deception or exaggeration.

Knowledge of advertising tactics and appeals becomes evident as children approach early adolescence (11–14 years of age) (Boush, Friestad, & Rose, 1994; Friestad & Wright, 1994; Paget, Kritt, & Bergemann, 1984). Although younger children may recognize that certain commercial features such as celebrity endorsers are meant to induce a positive reaction, they do not have an explicit understanding of how these features link to persuasion (Lawlor & Prothero, 2003) and underestimate the wide variety of commercial features (e.g., jingles, contests, animation) used by advertisers to persuade (Mallalieu, Palan, & Lacznia, 2005). To illustrate, Moore and Lutz (2000) found that younger children (ages 7–8) evaluated commercials based on their liking of the advertised product, whereas older children (ages 10–11) viewed advertisements in a more analytical nature, often focusing on creative content and execution (e.g., repetition and jingles).

Specific knowledge of advertising tactics and appeals continues to develop during adolescence, as documented in a study of sixth through eighth graders by Boush et al. (1994). Sixth through eighth graders were asked a series of questions about what advertisers are trying to accomplish when they use particular tactics, such as humor, celebrity endorsers, and product comparisons. Students were asked to rate eight possible effects (e.g., “grab your attention” and “help you learn about the product”) for each tactic. The results indicate that knowledge of advertising tactics increases with age, becoming more adult-like as children enter their teenage years. This developmental path is consistent with our characterization of children in the reflective stage, who possess substantial perspective-taking skills that allow them to reason about different perspectives (advertiser and viewer) across different contexts or situations.

Thus, adolescents view advertising in a more skeptical, analytical, and discerning fashion. However, it is also the case that adolescents find advertising to be entertaining, interesting, and socially relevant. By virtue of their growing sophistication, older children and adolescents find entertainment in analyzing the creative strategy of many commercials and constructing theories for why certain elements are persuasive (Moore & Lutz, 2000). Advertisements are also valued as a device for social interaction, serving as a focus of conversations with peers, a means of belonging and group membership, and a conduit for transferring and conveying meaning in their daily lives (Ritson & Elliott, 1999).

Product and Brand Knowledge

Brand knowledge continues to develop as children move from middle childhood into adolescence. Awareness and recall of brand names continues to increase, for both child-oriented product categories as well as more adult-oriented ones (Keiser, 1975; Ward et al., 1977). This is to be expected as adult-oriented products—such as cars, computers, and cameras—become more relevant to older children who are potential consumers for these items.

More interesting, however, are the developments that occur in children's understanding of the symbolic meanings of products and brands. As discussed earlier, understanding of consumption symbolism begins to emerge by second grade, but is not well developed until sixth grade. This is especially true for understanding symbolic meanings attached to brands. Illustrative is a study with second graders, sixth graders, and high school students reported by Achenreiner and John (2003). Participants were shown ads for a pair of athletic shoes, which pictured an identical pair of shoes labeled as being either Nike (preferred brand) or Kmart (non-preferred brand), and gave their impressions of the owner of the athletic shoes. Second graders had similar impressions of the owners regardless of brand name. In contrast, sixth graders and high school students had impressions of the owner of the Nike shoes that were more positive (e.g., more popular, smarter) than those for the owner of the Kmart shoes.

Thus, by sixth grade, children are developing a keen sense of the social meaning and prestige associated with brands. Further, brands not only confer status to their owners, but also begin to symbolize group identity and a sense of belonging to certain groups (Jamison, 1996). These developments are consistent with our description of children in the reflective stage, who form impressions based on social comparisons of factors such as personality, social standing, and possessions.

Shopping Knowledge and Skills

Despite the fact that children understand many aspects of the shopping environment by middle childhood, they have relatively undeveloped notions about pricing until they reach adolescence. By the time children are 8 or 9 years old, they know that products have prices, know where to look for price information, and know that there are price variations among products and stores (McNeal & McDaniel, 1981). But, they have fairly simple notions of how these prices reflect supply and demand in the marketplace. Adults, for example, see prices as a reflection of the utility or function of the item to the consumer, the costs of inputs incurred by the manufacturer to make the item, and the relative scarcity of the item in the marketplace (Fox & Kehret-Ward, 1985).

Not until early adolescence do children perceive a full range of connections between price and value (Berti & Bombi, 1988; Fox & Kehret-Ward, 1985). A study by Fox and Kehret-Ward (1990), where children were asked to explain the basis of prices for selling a bicycle, provides a nice illustration. Preschoolers focused on a product's perceptual features, especially size, as the basis for pricing, but did not articulate a theory for why these features provide more value. Ten-year-olds linked price to perceptual features (size or fancy features), but reasoned that a higher price would be present due to the amount of production inputs required. Only 13-year-olds exhibited a more abstract level of reasoning, viewing prices as a function of the quality of the product's inputs and preferences of potential buyers.

Decision-Making Skills and Abilities

During the adolescent years, several changes occur in the use of information sources. Older adolescents seek out additional sources of information, generally favoring peers and friends over parents and mass media (Moore & Stephens, 1975; Moschis & Moore, 1979; Stephens & Moore, 1975; Tootelian & Gaedeke, 1992). They develop a greater ability to ignore irrelevant information, focus on more relevant information (Davidson, 1991b), use attribute information in forming preferences and making choices (Capon & Kuhn, 1980; Klayman, 1985; Nakajima & Hotta, 1989), and apply decision-making strategies more appropriately to make better choices (Bereby-Meyer, Assor, & Katz, 2004; Howse, Best, & Stone, 2003).

The most important development during adolescence is the ability to adapt decision-making strategies to more complex decision environments, which include more choice alternatives and more information per alternative. Adult decision makers adapt to more complex environments in several ways, including restricting search to a smaller percentage of the available information, focusing their search on more promising alternatives, and switching from compensatory choice strategies to noncompensatory ones that are less cognitively demanding (see Payne, Bettman, & Johnson, 1993). These adaptive responses develop in children as they approach adolescence, being consistently exhibited by the time children reach 11 or 12 years of age (Davidson, 1991a, 1991b; Gregan-Paxton & John, 1997; Klayman, 1985). Children's abilities undergo further refinement as they move into late adolescence, using a wider array of simplifying strategies in a more systematic manner (Nakajima & Hotta, 1989).

Illustrating these developments is a study by Davidson (1991a), conducted with second, fifth, and eighth graders. Children made choices from alternatives described on an information board. Four information boards varying in complexity were shown: 3 (alternatives) \times 3 (dimensions), 3 \times 6, 6 \times 3, and 6 \times 6. Information about each alternative was hidden from view by a card, but children were allowed to uncover as much information as they wanted prior to choice. As complexity increased, older children (fifth and eighth graders) were more efficient in gathering information, searched less exhaustively, and exhibited a greater use of noncompensatory strategies. In particular, these children appeared to be using conjunctive decision rules, consistent with Klayman's (1985) findings. In contrast, younger children (second graders) responded to increasing complexity by making smaller adjustments in their search strategies without using a consistent simplifying strategy such as the conjunctive rule.

Purchase Influence and Negotiation Strategies

By the time they reach early adolescence, children have an extended repertoire of influence strategies available to them (Kim, Lee, & Hall, 1991; Manchanda & Moore-Shay, 1996; Palan & Wilkes, 1997). These strategies are more sophisticated, appealing to parents in seemingly rational ways, and are used in a flexible manner to match the situation or answer the objection of a parent. Palan and Wilkes (1997) provide an illustration of this growing sophistication in a study conducted with 12- to 15-year-olds and their parents. Using interviews, the authors identified a diverse set of purchase influence strategies used by adolescents: (1) bargaining strategies, including reasoning and offers to pay for part of the purchase; (2) persuasion strategies, including expressions of opinions, persistent requesting, and begging; (3) request strategies, including straightforward requests and expressions of needs or wants; and (4) emotional strategies, including anger, pouting, guilt trips, and sweet talk.

Bargaining and persuasion were favorites among the group of adolescents, with emotional strategies favored least. Variations in frequency appear to be driven, in part, by which strategies adolescents perceive to be the most effective in obtaining desired items. Strategies such as reasoning and offers to pay for part of an item are seen as very effective; strategies such as begging and getting angry are seen as least effective. Adolescents also adapt the strategies they use depending on what they view as most effective in influencing parents. One way of doing so is by duplicating the strategies used by their parents for responding to their purchase requests. For example, adolescents perceived reasoning as the most effective influence strategy when they came from families where parents reported the frequent use of reasoning strategies. Also perceived as effective were influence strategies that had a logical connection with the objections parents raised to a purchase request. For example, in families where parents often refused purchase requests by stating the family could not

afford the item, adolescents knew it was effective to use strategies that reduced the monetary outlay, such as offers to pay for part of the item.

Consumption Motives and Values

With a keen sense of the social meanings and status according to material possessions, teenagers are strongly motivated by social considerations in purchasing goods and services. Certain products and brand names not only confer status to their owners, but also begin to symbolize group identity and a sense of belonging to distinct social groups. Products such as clothing are particularly notable in this regard, as reported by Jamison (1996) in a study with children ages 11–12. Clothes are described as a means of fitting in and as a way to identify membership in a particular subgroup, such as the “preppies” and “hip-hops.”

Chaplin and John (2005) provide an illustration of social motivations for consumption linked to self-identity in a study with 8- to 18-year-olds. Participants were asked to construct a collage, using a set of pictures and words, to answer the question, “Who Am I?” Provided were pictures and words referring to specific hobbies, sports, personality traits, TV/movie characters, and brand names. Results indicated that older children (ages 12–18) included more brands on their collages than did younger children (ages 8–9). In addition, teenagers explained these self-brand connections in social terms, describing how certain brands exuded their personality or group affiliation, whereas younger children made self-brand connections on a more concrete basis (e.g., owning an item with the brand). Thus, for teenagers, social motivations for owning brands are strong because brands are seen as reflecting one’s self-concept.

Not surprisingly, social motivations for consumption are associated with higher levels of materialism. A recent study by Chaplin and John (2007) suggests that materialism increases as children move into their adolescent years. Children 8 to 18 years old were asked to construct a collage to answer the question, “What makes me happy?” For this purpose, participants were given a set of pictures and words, which included non-material themes (e.g., friends, good grades, hobbies) and material goods (e.g., money, computer games, brands). Children in the middle age group (ages 12–13) selected more material goods for their collages than either the youngest (ages 8–9) or oldest (ages 16–18) age groups. Given that happiness is an instrumental goal associated with materialism, these findings suggest that children just entering adolescence exhibit the strongest materialistic tendencies. Interestingly, these tendencies are somewhat abated in older adolescents, who begin to focus more on achievements (e.g., good grades, getting into a good college) than material goods as a means for achieving happiness.

CHALLENGES FOR FUTURE RESEARCH

Our framework views consumer socialization as progressing in a series of three stages—perceptual, analytical, and reflective—described by changes in children’s knowledge and skills during childhood and adolescence. We have reviewed empirical evidence consistent with these stages, documenting children’s growing sophistication about products, brands, advertising, shopping, pricing, decision-making strategies, influence approaches, and consumption motives and values (see Table 8.2). It is also the case, however, that significant gaps remain in our understanding of these stages of consumer socialization. These gaps, in topic areas as well as research methodologies, constitute challenges for future research.

Table 8.2 Summary of Findings by Consumer Socialization Stage

Topic	Perceptual stage, 3–7 years	Analytical stage, 7–11 years	Reflective stage, 11–16 years
Advertising knowledge	Can distinguish ads from programs based on perceptual features	Can distinguish ads from programs based on persuasive intent	Understand persuasive intent of ads as well as specific ad tactics and appeals
	Believe ads are truthful, funny, and interesting	Believe ads lie and contain bias and deception — but do not use these “cognitive defenses”	Believe ads lie and know how to spot specific instances of bias or deception in ads
	Positive attitudes toward ads	Negative attitudes toward ads	Skeptical attitudes toward ads
Product and brand knowledge	Can recognize brand names and beginning to associate them with product categories	Increasing brand awareness, especially for child-relevant product categories	Substantial brand awareness for adult-oriented as well as child-relevant product categories
	Perceptual cues used to identify product categories	Underlying or functional cues used to define product categories	Underlying or functional cues used to define product categories
	Beginning to understand symbolic aspects of consumption based on perceptual features	Increased understanding of symbolic aspects of consumption	Sophisticated understanding of consumption symbolism for product categories and brands
	Egocentric view of retail stores as a source of desired items	Understand retail stores are owned to sell goods and make a profit	Understanding and enthusiasm for retail stores
Shopping knowledge and skills	Understand sequence of events in the basic shopping script	Shopping scripts more complex, abstract, and with contingencies	Complex and contingent shopping scripts
	Value of products and prices based on perceptual features	Prices based on theories of value	Prices based on abstract reasoning, such as input variations and buyer preferences
Decision-making skills: Information search	Limited awareness of information sources	Increased awareness of personal and mass media sources	Contingent use of different information sources depending on product or situation
	Focus on perceptual attributes	Gather information of functional as well as perceptual attributes	Gather information on functional, perceptual, and social aspects
	Emerging ability to adapt to cost-benefit trade-offs	Able to adapt to cost-benefit trade-offs	Able to adapt to cost-benefit trade-offs

(Continued)

Table 8.2 Continued

Topic	Perceptual stage, 3–7 years	Analytical stage, 7–11 years	Reflective stage, 11–16 years
Product evaluation	Use of perceptually salient attribute information	Focus on important attribute information – functional and perceptual attributes	Focus on important attribute information – functional, perceptual, and social aspects
	Use of single attributes	Use two or more attributes	Use multiple attributes
Decision strategies	Limited repertoire of strategies	Increased repertoire of strategies, especially noncompensatory ones	Full repertoire of strategies
	Emerging ability to adapt strategies to tasks – usually need cues to adapt	Capable of adapting strategies to tasks	Capable of adapting strategies to tasks in adult-like manner
Purchase influence and negotiation strategies	Use direct requests and emotional appeals	Expanded repertoire of strategies, with bargaining and persuasion emerging	Full repertoire of strategies, with bargaining and persuasion as favorites
	Limited ability to adapt strategy to persons or situations	Developing abilities to adapt strategy to persons and situations	Capable of adapting strategies based on perceived effectiveness for persons or situations
Consumption motives and values	Value of possessions based on surface features, such as “having more” of something	Emerging understanding of value based on social meaning and significance	Fully developed understanding of value based on social meaning, significance, and scarcity

Consumer Socialization Topics

Advertising and Persuasion Knowledge. Due to concerns about advertising to young children, researchers have focused their attention on children under the age of twelve. We know a great deal about how an understanding of advertising develops in children prior to adolescence. However, we still have much to learn about developments during adolescence. The few studies including adolescents suggest that important developments occur during this period, such as a more sophisticated understanding of specific advertising tactics, types of bias, and social context. Further examination of these topics would contribute to our understanding of how persuasion knowledge develops, as well as providing insight for public policy concerns about adolescent response to advertising for products such as cigarettes and alcoholic beverages.

Further research would also be welcome to explore how advertising and persuasion knowledge is utilized in children’s responses to persuasive communications (Wright, Friestad, & Boush, 2005). Existing research focuses on what children know or believe about advertising, assuming that once advertising knowledge is acquired, it will be used as a cognitive filter or defense when children are exposed to persuasive messages. Yet, the few studies that examine how advertising knowledge is actually used by children in viewing situations suggests that more attention should be paid to

understanding when such knowledge is accessed and used. The evidence to date suggests that cognitive filters and defenses against advertising may emerge during early adolescence, providing yet another reason for more attention to developments during the reflective stage.

Product and Brand Knowledge. Perhaps the greatest challenge in this area is a better understanding of how children relate to brands at different stages. Consumption symbolism is an important topic, yet the few studies addressing this issue focus on products, not brands. Although few in number, studies of children's relationships with brands suggest that important changes occur with the approach of adolescence. Current research points to important qualitative changes in the way adolescents view brands, yet we lack descriptive detail about the nature of these changes. Brand relationship frameworks (Fournier, 1998) would be especially useful in describing how these relationships develop from adolescence to adulthood.

Shopping Skills. Despite the acknowledgement that children become enthusiastic shoppers at a young age, research is needed to understand the development of shopping skills, involving comparisons between prices, volumes, sizes, and the like. Surprisingly, we were unable to locate a single study focused on this topic within the last twenty years. Given the large body of research in child psychology on children's developing mathematical abilities and strategies (see Siegler & Jenkins, 1989), it would appear to be an opportune time to revisit issues related to shopping skills. A related topic, children's understanding of pricing and value, would also be a natural candidate for further research. Both topics would be welcome additions to our knowledge about the analytical stage, when mathematical abilities and abilities to integrate information converge, producing a situation conducive to major improvements in shopping skills.

Decision-Making Skills and Abilities. Perhaps the most noticeable gap in this literature is a basic understanding of what decision strategies children possess at different ages. Exploring the age at which children effectively utilize compensatory and noncompensatory strategies would be particularly important. Existing research provides some clues, but empirical data is particularly limited for younger children in the perceptual stage.

Also important would be research exploring decision-making goals. To date, research has proceeded as if children shared the same decision-making goals as adults, such as buying the "best" product or making a good decision with the least cognitive effort. It may well be that young children have quite different goals in mind, such as choosing a novel product, being surprised, or having fun. This may, in fact, provide a richer explanation for some of the findings regarding age differences in decision-making skills and behavior.

Purchase Influence and Negotiation Strategies. Investigations using in-depth interviews have provided vivid examples of the growing sophistication of older children and adolescents. Observational research, often conducted in grocery stores, has provided a picture of influence attempts for very young children accompanying their parents to the store. What is missing is research focused on children between these age groups, primarily children in the analytical stage between the ages of 7 and 11. As we have seen, much social development occurs during this period and it would be useful to track how changes in areas such as social perspective taking facilitate the development of purchase influence and negotiation strategies.

Also useful would be research looking at the connection between influence and negotiation strategies and other aspects of children's consumer knowledge and behavior. One example would be the relationship between purchase influence strategies and advertising knowledge. Although these areas have existed independently, they both deal with persuasion—how to persuade someone else or how someone tries to persuade you. Another example would be the relationship between purchase influence and negotiation strategies and parent-child conflict, sometimes viewed as a negative effect of advertising to children.

Consumption Motives and Values. Until recently, adolescents have been the focus of most research in this area. Studies including younger children are just beginning to emerge. As we have seen, perspective taking and impression formation undergo dramatic development from middle childhood to adolescence. These developments in social understanding are probably linked to important changes in views of consumption, yet we have little descriptive detail to identify the nature of these changes. Studies with children in the analytical stage (ages 7-11) would be useful in understanding the relationship between social and cognitive development and aspects of consumption motives and values.

Methodological Approaches

In addressing gaps in our knowledge, there are also challenges in designing appropriate methodologies for studying consumer socialization across a wide age range. Sample design, stimuli selection, and measurement design are issues common to researchers working with children of any age.

First, in terms of sample design, selecting the appropriate age groups can present difficulties. Often, researchers are addressing a specific question for the first time, without prior research to guide sample selection. Concerns about selecting age groups that will uncover developmental patterns, if they exist, are common. Questions about the youngest or oldest age group that should be included are often involved. Guidance on these issues is available by using the stages of consumer socialization described here. For example, if the socialization topic under inquiry involves abstract thinking or integration of multiple pieces of information, the sample should include children in the perceptual (ages 3-7) and analytical (ages 7-11) stages. If the socialization issue being addressed involves social awareness and impression formation, the sample should include children in the analytical (ages 7-11) and reflective (ages 11-16) stages.

Selection of experimental stimuli also requires careful consideration. Unless the age range being examined is quite narrow, the researcher will need to be aware of age differences in familiarity, relevance, and interest in stimuli such as advertisements, product categories, brands, choice situations, and tasks. Tailoring the stimuli to each age group will not work if the objective is to compare age groups. The best solution is to find stimuli that are familiar and appeal to children across age groups. If this is not possible, which is likely for studies spanning a wide age range, the next best solution is to find stimuli that are familiar and appealing to the youngest age group, while holding some appeal to the oldest age group. The selection is tipped in favor of younger children because it is usually this age group that is found to have a lower level of ability or skills than older children; therefore, it is important to rule out the possibility that unfamiliarity or disinterest with the stimuli contributed to younger children's poorer performance on a task. In situations where collections of stimuli are required, such as clothing brand names, a mixture of brands can be used that are of interest to younger children (e.g., Limited Too), older children (e.g., Express), and children of all ages (e.g., Nike).

Designing measures to assess consumer knowledge, skills, or values is perhaps the most pressing problem in moving research forward in this area. In the past, researchers have used a mixture of traditional techniques, with emphasis on rating scales, recall and recognition measures, and unstructured interview questions. Adjustments are often made to accommodate young children, but measurement concerns persist in using these techniques. Unstructured questions require greater verbalization abilities than many young children have at their disposal. Added to this is the fact that many of the unstructured questions are rather abstract, without the concreteness that dominates thinking for children under 8 years of age. For example, questions such as "What is the purpose of advertising?" are far too abstract for children in the perceptual stage.

Rating scales reduce problems with verbalization, but present a different set of issues. Even for simple evaluative scales, such as a 1–5 smiley face scale, there are concerns that young children use only the extreme scale points (Karsten & John, 1994). For more complex scales, researchers often design statements that can be easily misinterpreted by young children. For example, in measuring materialism, we might ask young children to agree or disagree with the following statement: “Money can buy happiness.” Although similar statements are used to measure materialism in adults, the meaning is different for young children. Youngsters often take the statement quite literally, agreeing with the statement because money can buy many things they like, such as candy and toys. Oddly enough, rating scales can also be problematic at the other end of the age continuum. Here, the issue centers on social desirability bias among teenagers that are eager to present a positive face to interviewers. For examples, statements such as “Money can buy happiness” are quite transparent in intent, which may be more of a concern with adolescents who are eager to answer in a socially acceptable fashion.

In light of these difficulties, more attention needs to be given to developing new measures and measurement techniques for children and adolescents. First, when using rating scales, more careful attention needs to be paid to validating the scales across age groups. Examples of recent efforts in this vein can be found in areas such as children’s attitudes toward advertising (Derbaix & Pecheux, 2003) and children’s materialism (Goldberg et al., 2003). Second, newer measurement techniques need to be developed to supplement more traditional forms of questioning. For example, collages have been particularly useful in measuring constructs such as children’s self-concepts and materialism (Chaplin & John, 2005, 2007). Young children are familiar with collages and can express themselves with modest amounts of verbalization; for older children, the collage task allows the researcher to be less transparent, diminishing social desirability bias. Finally, researchers need to seek out opportunities to assess children’s consumer behavior in more naturalistic settings. Examples include studies of children’s requests for Christmas presents (Otnes et al., 1994) and decision-making research using choice games and gift choices (Gregan-Paxton & John, 1995; Wartella et al., 1979).

These methodological challenges dictate a degree of creativity and attention to detail far beyond those ever encountered in research with adult consumers. However, the rewards are considerable. Understanding consumer socialization will continue to be a topic of importance for many reasons. No other area of consumer behavior research is so focused on the process and outcomes of consumer learning that evolve over time. No other consumer segment has changed as much in purchasing power and influence in the last decade than the children and teen segment. Finally, there is probably no topic in consumer research that holds as much interest from a public policy and societal perspective, especially given recent concerns over the consumption of alcohol, tobacco, and unhealthy foods. We look forward to meeting the challenges to produce a greater understanding of consumer socialization in the future.

Aging and Consumer Behavior

CAROLYN YOON

University of Michigan

CATHERINE A. COLE

University of Iowa

INTRODUCTION AND BACKGROUND

Until recently, most businesses and marketing researchers have virtually ignored the older market. Perhaps this neglect stemmed from inaccurate stereotypes about older consumers so that they were routinely written off as poor, overly frugal, or already set in their loyalty to brands. These stereotypes about older people, however, appear to be falling slowly by the wayside. For example, recent research conducted by the American Association of Retired Persons (AARP) suggests that for most products, the majority of older adults are not loyal to a single brand (AARP Report, 2002).

Increasingly, businesses, governmental agencies, and researchers are recognizing that older consumers comprise a segment that is generally substantial, identifiable, and accessible—key requirements for selecting target segments. For example, in the business area, the travel industry has found that compared to other age groups, senior travelers are an important target market because of their relative wealth, discretionary income, low consumer debt, and available free time (Littrel, Paige, & Song, 2004).

Today, there are about 35 million people over the age of 65; by 2010, this number is expected to reach 50 million. By the year 2020, one out of every six Americans will be 65 or older. Whereas the U.S. population used to be represented by a pyramid, with a broad young base that tapered off to a point at the top with extreme age, we have in more recent years seen a “rectangularization” of the age pyramid with greater life expectancy and lower birth rates (Long, 1998).

Not only is the size of the senior population increasing, its financial and health characteristics are improving. For example, the AARP reports that in the past decade, Americans aged 50 and over have seen their economic status improve where status is measured in terms of median inflation adjusted income and household financial assets. Additionally, in the same time period, the proportion of family budgets available for discretionary items has increased for the 50+ population overall (AARP Report, 2005).

Technological Changes

Contrary to stereotypes, older adults appear to be interested in using new technologies (Rogers & Fisk, 2000). However, learning to use new technological products may provide particular challenges to the elderly. Rogers, Meyer, Walker, and Fisk (1998) conducted a focus group study of healthy and active older adults (aged 65 to 88) in which they investigated the effects of changes in the environment and new technology. They found that the elderly faced a variety of challenges from new technologies; participants reported problems with a broad range of technologies including answering machines, home security systems, computerized telephone menus, multiple-line telephones, and computers.

For many years, marketing practitioners thought that older adults lagged behind younger adults in adopting new technologies. However, recent data suggest that this belief may be based on a negative stereotype rather than reality. Studies, investigating how age and attitudinal characteristics affect consumers' willingness to adopt new products, found that older consumers were as likely, or more likely, to adopt some new technological products (e.g., automatic bill payment, electronic funds transfer; Gilly & Zeithaml, 1985; Kolodinsky, Hogarth, & Hilgert, 2004). The studies concluded that like other consumers, seniors do purchase product innovations when they possess clear benefits and meet specific needs.

As older consumers encounter new technologies, they may be vulnerable to fraudulent marketing practices. On the one hand, older consumers may develop greater persuasion knowledge than younger adults through experience. Persuasion knowledge is knowledge about persuasion tactics and methods of resisting persuasion attempts (Friestad & Wright, 1994). With this rich knowledge base, older consumers should be able to resist persuasive efforts better than younger consumers. On the other hand, unlike younger adults, older consumers may not easily update their persuasion knowledge as technology changes. In addition, recent empirical work indicates that when cognitive capacity is constrained, younger consumers are less likely to recruit persuasion knowledge (Campbell & Kirmani, 2000). Thus, older adults, who may have more limited processing capacity than younger adults, may have difficulty using their persuasion knowledge, especially if the information is presented rapidly on a new technology (e.g., an advertisement on the Internet). As a result, new research is needed on the circumstances in which older adults can recruit relevant persuasion knowledge to resist persuasion efforts.

Hearings before the U.S. Senate's Special Committee on Aging (2000), which focused on Internet fraud and seniors, revealed that 59% of people aged 50 to 64, and 22% of those over 65, had become Internet users. Unfortunately, law enforcement agencies have witnessed a growth in reports of older adults being taken in by fraudulent online activities such as identity theft, "phishing" schemes in which criminals set up emails and websites designed to look like those of legitimate companies and financial institutions, nondelivery of merchandise, and investment fraud.

Heterogeneity of Older Adults

Older adults comprise a heterogeneous group. At a minimum, there are important cohort differences among seniors of different ages. For example, older adults who are currently in their mid-80s grew up during the Depression era, whereas those in their 60s and 70s reached adulthood during the post-World War II era, a period that was characterized by greater consumerism.

In the developmental psychology literature, researchers have distinguished among "young-old" (65 to about 75 years), "old-old" (75 to about 85) and "very-old" or "oldest-old" (over 85; e.g., Smith & Baltes, 1997). While most "young-old" people remain in relatively good health, physical decline

usually becomes more evident in the “old-old” and may progress rapidly among the “very-old.” These distinctions notwithstanding, there is no set agreement regarding the age at which a person is considered “old.” Although in the consumer domain, an older person has been most commonly defined as someone over 65 years old, others have defined older adults as those over 60, and some have even begun considering those over 50 as senior consumers.

Segmentation schemes for the mature market might include age, income, education, personality and lifestyle variables. Along these lines, the Center for Mature Consumer Studies has developed a segmentation model known as “gerontographics” which segments the mature market based on aging processes and life circumstances (Moschis, 1996). Consumer behavior, such as patronization of specific food or grocery stores, has been found to vary across these gerontographic segments (Moschis, Curasi, & Bellenger, 2004).

Despite growing interest in the topic of older consumers, there are still relatively few studies that focus on aging and consumer behavior. In this chapter, we consider the aspects of aging that seem particularly relevant for consumer behavior and identify promising avenues for future research. In doing so, we provide a selective review of the literature that informs our understanding of older adults in consumer contexts. In particular, we discuss some physiological, cognitive, and socio-emotional changes that accompany aging and consider their implications for consumer decision making.

PHYSIOLOGICAL CHANGES

As people age, they experience physiological changes which, in turn, can affect the way they interact with the consumer environment. Problems with visual and auditory functions increase markedly with age, typically beginning in the fourth decade of life (Schieber & Baldwin, 1996; Willott, 1991). These changes can have dramatic effects on older adults’ attention and cognition. In many cases, it may not be possible to fully restore visual and auditory functions to levels of younger adults through surgery or use of prostheses (e.g., contact lenses, eyeglasses, hearing aids). Motor control also declines in older adults. These declines include changes in the peripheral and central nervous system, and changes in control and coordination of motor functions that can lead to an array of behavioral decrements (Ketcham & Stelmach, 2003).

Vision

Approximately half of all adults over 65 years old have cataracts (Fozard & Gordon-Salant, 2001). As people age, size of the pupil declines and the lens becomes more opaque (Weale, 1961). The loss of transparency is particularly pronounced for short wavelengths (e.g., blue, green light) due to age-related yellowing of the lens. Moreover, age-related declines in visual acuity (an indicator of how well fine spatial detail can be recognized) become more severe when there is low luminance or the stimuli are low in contrast. However, color constancy mechanisms appear to remain relatively intact in older adults, possibly minimizing decrements on familiar real-world tasks performed in well-lighted conditions.

Age-related changes in vision suggest that the way in which information is presented or displayed can affect whether or not it is processed. For instance, messages and displays that appear clear, bright, and attractive to a younger person are likely to be fuzzy, dark, and unpleasant to an older one. In most cases, better illumination, higher contrasts, and reduced glare will help older consumers. Also because older adults tend to make less use of their peripheral fields than younger adults, managers may wish to place brands close to consumers’ direct line of sight in retail environments.

Hearing

Older adults find it progressively more difficult to detect simple, low-intensity sounds, discriminate small changes in frequency or intensity, filter out background noise, and identify the source of a target noise in space (Schneider & Pichora-Fuller, 2000). Older adults in conversations also have more difficulty processing phonemes than syllables. These changes are not only likely to compromise listening, but they can negatively affect the ability to encode information in many consumer situations. It suggests that sound and sound clutter can be problematic for older adults in consumer environments over which they do not have control.

Motor Functions

Motor behavior refers to muscular actions performed to fulfill some objective of the performer (e.g., braking a car, pushing lawn mower, hitting a golf ball). Normally aging people are capable of performing many motor behaviors in everyday life well into their 80s. However, they have much slower reaction times, in some cases as much as 50% slower on complex tasks (Cerella, 1990; Salthouse, 1996).

Age-related changes in motor functions have important implications for product design and usability in consumer domains. For example, individual programming of devices becomes increasingly difficult due to declines in vision and poorer ability to handle very small objects. Use of a computer mouse has been found to pose a major impediment to computer usage among older adults (Walker, Philbin, & Fisk, 1997). It is thus important that there be development of more user-friendly means by which older adults can interface with smaller gadgets including items such as hearing aids and cell phones. A few studies have investigated the benefits of devices that improve the speed and accuracy of movements as well as coordination and balance in older adults (e.g., Maki et al., 1999). However, much work remains to be done in the design and development of assistive devices and technologies.

MEMORY

Another arena in which there is a great deal of age-related changes is memory processes. Although there is widespread agreement that aging negatively affects performance on most memory tasks, there is not as much consensus about when and why age-related differences in memory occur (Craik & Jennings, 1992; Kausler, 1994; Light, 1991; Schaie, 2005). Memory impairments that have been documented in the laboratory may not necessarily extend to everyday domains of behavior (Zacks, Hasher, & Li, 2000). In addition, not all aspects of memory are impaired (e.g., Rahhal, May, & Hasher, 2002; Schacter, Kihlstrom, Kaszniak, & Valdiserri, 1993). In this section we review the literature with respect to changes in memory.

Theoretical Perspectives

Three main theoretical perspectives have been advanced to account for age-related memory changes: speed of processing (e.g., Salthouse, 1996), reduced processing resources (e.g., Craik, 1986), and diminished inhibition (e.g., Hasher & Zacks, 1988). Although the theoretical accounts do share substantial conceptual overlap, they have tended to be discussed separately in the literature. Each is considered in turn, along with a discussion of empirical studies from psychology, neuroscience, and marketing that shed light on cognitive functioning of older adults.

Speed of processing

According to the speed of processing view, aging is accompanied by a general slowing of mental functioning (Cerella, 1985). There is substantial evidence that speed of working memory slows down across the lifespan (Salthouse, 1996). In particular, Salthouse argues that general processing speed serves as a mediator between age and cognitive performance on a variety of tasks. Although it is clear that older adults process information at a slower rate than younger adults, and that speed is an important explanatory variable, it is unlikely to provide a comprehensive theoretical account of cognitive aging. Factors other than speed (e.g., executive functions) frequently emerge as significant mediators of age-related differences in memory and fluid-intelligence tasks. For example, Hedden and Yoon (2006) found significant age differences in performance on tasks requiring critical executive functions such as shifting between relevant goals and/or updating representations in working memory.

Reduced processing resources

The reduced processing resources view arguably represents the most dominant theoretical account of age-related changes in memory performance (Craik, 1983, 1986). It suggests that reduced cognitive resources impair older adults' ability to engage in more cognitively demanding strategies such as deep, elaborate encoding operations which facilitate later memory retrieval (e.g., Cole & Houston, 1987; Craik & Byrd, 1982; Law, Hawkins, & Craik, 1998; Yoon, 1997).

A substantial proportion of the age-related decline in cognitive resources has been explained by deterioration in working memory (the ability to process small amounts of information for short periods of time while engaging in ongoing cognitive activities such as reading, listening, problem solving, reasoning or thinking) (Moscovitch & Winocur, 1992). In studies assessing span measures which are often taken as indicators of working memory capacity, older adults perform reliably worse than younger adults (Verhaeghen, Marcoen, & Goosens, 1993).

Age-related changes in working memory are associated with changes in executive functions (see West, 1996, for a review; Craik & Jennings 1992; Park et al., 1996). Executive functions of cognition are defined as the ability to schedule and optimize subsidiary processes. They include such mechanisms as shifting between active and inactive rules or task goals, updating the current contents of working memory to reflect task-relevance, and the inhibition or suppression of inappropriate or prepotent responses (Andrés 2003; Aron, Robbins, & Poldrack, 2004; Miyake et al., 2000). Recent neuroimaging evidence suggests that executive subcomponent mechanisms rely on distinct neural regions within a shared frontal-parietal network, the very same regions that are the most highly affected during the developmental processes of normal aging (see Hedden & Gabrieli, 2004, for a review).

A common finding is that across the adult lifespan, the prefrontal cortex exhibits volumetric declines that are larger than those in many connected regions, including parietal cortex and medial temporal structures such as the hippocampus and amygdala. Indeed, the largest age-related volume declines are in the lateral prefrontal cortex, which is functionally implicated in a variety of executive function tasks. Although the lateral prefrontal cortex is unlikely to be the sole site of executive processes, it is undoubtedly an important part of the neural circuits underlying several executive functions (Fuster, 2002). Supporting this interpretation, older adults display deficits in performance on a variety of neuropsychological tests of executive function (Bryan & Luszcz, 2000).

The similarity between the behavioral deficits exhibited by frontal patients with dysexecutive syndrome and those exhibited by healthy older adults led to the development of the frontal aging

hypothesis (Moscovitch & Winocur, 1995; West, 1996). According to this hypothesis, age-related declines in prefrontal structures impair the ability of older adults to monitor and control processes subserved by other brain regions that may be less affected by normal aging (Hedden & Gabrieli, 2004). In support of this hypothesis, several neuroimaging studies have found that age-related changes in functional activity in the prefrontal cortex are associated with changes in activity in posterior and medial temporal regions during the performance of tasks of executive control in working memory and successful episodic encoding (Daselaar, Veltman, Rombouts, Raaijmakers, & Jonker, 2003; Grady, McIntosh, Bookstein, Horwitz, Rapoport, & Haxby, 1998; Gutchess et al., 2005).

Thus the neural and behavioral data appear to point to particular difficulties for older consumers on tasks that draw on the ability to maintain and manipulate information in working memory. For example, tracking and integrating new product information is likely to be challenging. Maintaining and manipulating multiple pieces of information in a noisy environments would also be more difficult for older than younger adults.

Interestingly, however, not all older adults exhibit marked declines in performance of executive function tasks. In fact, some older adults perform nearly as well as their younger counterparts (e.g., Hedden & Park, 2003). These “successful agers” tend to exhibit high performance on neuropsychological tasks thought to measure frontal functions (Glisky, Rubin, & Davidson, 2001). High performing older adults have been found to engage the prefrontal cortex regions bilaterally; and this has led to suggestions that high-performing older adults may counteract age-related neural decline by recruiting through a plastic reorganization of neurocognitive networks (Cabeza et al., 1997; Reuter-Lorenz et al., 2000).

Diminished inhibition

The third major theoretical account of age-related memory changes posits that inhibitory processing is impaired for older adults (Duchek, Balota, & Ferraro, 1995; Hasher & Zacks, 1988). The inhibitory framework assumes that the occurrence of familiar stimuli in the environment will activate the associated linkages including those irrelevant to the task at hand. Among those representations that have received some degree of activation, conscious awareness is assumed to be restricted to the most highly activated subset (cf. Cowan, 1988; 1993), which is referred to as the contents of working memory (Hasher, Zacks, & May, 1999).

Inhibitory mechanisms are critical for controlling the contents of working memory. They enable efficient on-line processing and subsequent successful retrieval of target information by preventing irrelevant information from entering working memory and deleting from working memory no longer relevant information. These two functions, access and deletion, minimize competition from distracting material during both encoding and retrieval, thus increasing the likelihood that items activated concurrently in working memory are relevant to one another, and that target information will be successfully processed and retrieved. Finally, inhibition operates to restrain strong responses from being emitted before their appropriateness can be evaluated. The restraint function of inhibition thus allows for the appraisal and rejection of dominant responses when they are undesirable, so that a less-probable but more suitable response can be produced.

There are direct consequences of diminished inhibition for cognition for older adults. For example, older individuals with impaired inhibitory functioning are susceptible to distracting, irrelevant information, whether that distraction is generated from external sources (e.g., from a radio program playing in the background) or internal sources (e.g., personal concerns) (Hartman & Hasher, 1991; Hamm & Hasher, 1992). This is particularly pronounced when people attempt to

retrieve proper names (Maylor, 1990) and is consistent with other evidence indicating that name retrieval failure is a frequent subjective complaint by older adults.

In addition, the inability to clear away previously relevant but currently inappropriate information may lead to heightened interference between relevant and irrelevant information for poor inhibitors, resulting in difficulties in acquiring new material, comprehending questions, and retrieving stored memories. Poor inhibitors may also have difficulty disengaging from one line of thought or activity and switching to another, as well as in preventing the production of well-learned responses when those responses are inappropriate. Prior studies have also shown that older adults are more susceptible to interference than younger adults in a variety of domains including dual-task interference (Verhaeghen, Steitz, Sliwinski, & Cerella, 2003), global task switching (Verhaeghen & Cerella, 2002), retroactive interference (the effect of new material on memory for old) in working memory (Hedden & Park, 2001; 2003), and proactive interference (the effect of old material on memory for new) in working memory (Bowles & Salthouse, 2003; Lustig, May, & Hasher, 2001; May, Hasher, & Kane, 1999) as well as long-term memory (Jacoby, Debner, & Hay, 2001).

These direct impairments, produced by deficient inhibitory functioning, may lead to other indirect cognitive consequences. Since lack of control over working memory also ultimately reduces the efficiency of retrieval, diminished inhibition efficiency can further lead to an increased reliance on stereotypes and use of heuristics in decision making, even in situations where detailed, analytical processing may be more appropriate.

Automatic vs. Controlled Processing

Prior empirical work on memory and aging suggests that while some aspects of memory performance decline with increasing age, other aspects of performance are relatively spared. For instance, we know that whereas episodic recall and source memory become poorer with increasing age (e.g., Spencer & Raz, 1995), semantic memory for well-learned or familiar information remains more intact (e.g., Morrow, Leirer, & Altieri, 1992; Zacks et al., 2000). Further, information that is implicitly learned or processed tends to be relatively spared across the lifespan (Howard & Howard, 1989; Light & Singh, 1987).

A way in which these patterns of findings have been interpreted is by distinguishing between automatic and controlled processes (see Zacks & Hasher, 1979). Automatic processes are considered to require little cognitive capacity (e.g., event frequency, word meaning), to be independent of conscious control, and to occur without deliberate effort. For example, studies comparing experts in chess, aviation, typing, and piano playing report preservation of expert knowledge in older adults (e.g., Krampe & Ericsson, 1996). Automatic processes do not interfere with ongoing cognitive activity and are relatively immune to the effects of increased age (cf. Light & Zelinski, 1983). By contrast, controlled processes place a strain on processing resources because they are intentionally and consciously processed and require effort. Given that effortful processing requires cognitive capacity that is reduced with age, memory tasks involving deliberate, self-initiated processing (e.g., free recall) is negatively affected by age (Craik, 1986; Craik, Anderson, Kerr, & Li, 1995).

These two processes have also been considered central to the idea underlying dual process models of memory. Within the dual process theories, the processes are, however, more commonly referred to as recollection and familiarity. Whereas recollection is typically considered as conscious, intentional, or attention demanding, familiarity is regarded as unconscious with low attentional requirements. Light, Prull, La Voie, and Healy (2000) recently conducted a meta-analysis of the evidence relating to the dual process view of memory in older adults and reported two main results. They found larger priming effects for younger than older adults. In addition, they found

that age differences in priming tasks were considerably smaller than in recall and recognition tasks. Hence the Light et al. findings are generally consistent with the dual process view of memory in older adults.

Contextual Perspectives and Moderators

Contextual factors can modulate the degree to which there are age-related memory decrements. This perspective reflects a more functional approach to understanding age-related memory impairments and is often considered in conjunction with the limited resources view (e.g., Craik, 1983; 1986). According to this viewpoint, memory performance is a function of the interaction of external and internal factors. The external factors represent the amount of environmental support available at encoding and retrieval. As such, environmental support is broadly construed and includes dimensions such as instructional guidance to engage in deeper processing at encoding, the availability of relevant information at encoding and retrieval, and the provision of external retrieval cues that might enhance direct access to memory traces. Greater environmental support might thus be represented by any factor that provides more processing resources for a given task.

Internal factors also affect the processing resources a person has available for encoding and retrieval. The presumed age-related reduction in processing resources means that older adults are less able than younger adults to perform effortful encoding and retrieval tasks. The resource-demanding operations include self-initiated processes such as generation of new connections among items in unfamiliar domains and free recall of unrelated items with poor retrieval cues. However, strong environmental support, in the form familiar tasks and availability of external cues can compensate for age-related impairments in self-initiated processing (Craik, 1983, 1986; Craik & Byrd, 1982; Craik & McDowd, 1987; Craik & Anderson, 1999). Other researchers have also suggested a contextualist perspective on memory and aging (e.g., Baltes, Cornelius, & Nesselroade, 1979; Sinnott, 1989). More recently, Hess (2005) has elegantly argued for an approach that accounts for a broader array of influences including goals and social contexts.

Picture memory

The contextual view is relevant for understanding picture memory as well. Picture memory is relatively spared with age perhaps because of the unique, contextually-supported nature of the information. Although highly perceptually or conceptually similar items will still be forgotten, pictures that are semantically meaningful and complex can be remembered equivalently by younger and older adults (Park, Puglisi, & Smith, 1986; Park, Royal, Dudley, & Morrell, 1988; Smith, Park, Cherry, & Berkovsky, 1990). These results suggest the importance of providing environmental support, such as semantically meaningful or vivid pictorial memory cues, in order to reduce the strain on limited processing resources in older adults (Craik, 1986; Craik & Jennings, 1992; Park, Smith, Morrell, Puglisi, & Dudley, 1990; Smith, Park, Earles, Shaw, & Whiting, 1998). Interestingly, the increased reliance of elderly adults on contextual cues suggests that they could be disproportionately influenced by contextual variables that may not affect the decisions of their younger counterparts.

Schemas and prior knowledge

Older adults appear to exhibit reliable biases in how they are influenced by preexisting knowledge and schemas (e.g., Hess, Flanagan, & Tate, 1993; Koutstaal & Schacter, 1997; Yoon, 1997). Schemas can sometimes contribute to distorted recollections of past events, even though they also perform important organizing functions in our cognitive lives (Mandler, 1979). However, schemas are important in guiding memory retrieval, promoting memory for schema-relevant information, and

allowing us to develop accurate expectations of events that are likely to unfold in familiar settings on the basis of past experiences in those settings (Alba & Hasher, 1983).

Memory for schemas or gist may also be fundamental to such abilities as categorization and comprehension and may facilitate the development of transfer and generalization across tasks (Reyna & Brainerd, 1995). These benefits notwithstanding, false recall and recognition often occur when people remember the semantic or perceptual gist of an experience but do not recall specific details. Older adults are particularly prone to commit false recall and recognition and misattribute a memory to an incorrect time, place, or person (Norman & Schacter, 1997; Tun, Wingfield, Rosen, & Blanchard, 1998).

Presenting information using rich, meaningful materials and in ways that build on elderly adults' network of semantic knowledge will lead to better memory to support choices, particularly when the material can be recognized rather than recalled. Material presented verbally or in event-based scenarios, by contrast, should be more poorly remembered. Due to better autobiographical memory for periods before and during young adulthood and the early organization of semantic knowledge structures, older consumers may have the most knowledge of product categories and brands that were available at this earlier point in their lives. This suggests that older adults may have greater ability than younger adults to process information about established compared to newer product categories and brands.

Source memory and misattribution

People may correctly remember an item or fact from a past experience but misattribute the fact to an incorrect source. For instance, individuals sometimes recall encountering a bit of trivia in the newspaper that, in fact, they acquired from an experimenter in a study (Schacter, Harbluk, & McLachlan, 1984). Similarly, older adults also have greater problems remembering what they actually said or did versus merely imagining doing so (Cohen & Faulkner, 1989; Johnson et al., 1993). Source confusions of this kind can be particularly pronounced in older adults (McIntyre & Craik, 1987). For example, Schacter et al. (1997) found that older adults often confused whether they had seen an everyday action in a videotape or only in a photograph that they viewed several days later, whereas younger adults had little difficulty remembering the correct source. Further, older adults have greater difficulty remembering whether the speaker was male or female (Bayen & Murnane, 1996), and whether the items were presented auditorially or visually (e.g., Light et al., 1992).

Individuals sometimes misattribute a spontaneous thought or idea to their own imagination, when in fact they are retrieving it—without awareness of doing so—from a specific prior experience. This type of misattribution is characterized by an absence of any subjective experience of remembering. Older adults are especially susceptible to such misattributions (Dywan & Jacoby, 1990). In a recent study, Skurnik, Yoon, Park, and Schwarz (2005) found that telling people that a consumer claim is false can make them more likely to misremember it as true. In two experiments, older adults were especially susceptible to this “illusion of truth” effect. Repeatedly identifying a claim as false helped older adults remember it as false in the short term, but paradoxically made them more likely to remember it as true after a three-day delay. This unintended effect of repetition was due to increased familiarity with the claim itself, but decreased recollection of the claim's original context.

Socioemotional factors and meaningfulness

Recent studies support the idea that certain contexts acquire special significance with age. In a study by Rahhal et al. (2002), older adults exhibited the typical source memory impairments for which of two speakers, Mary or John, uttered a statement. However, when the information was pre-

sented in more social or emotional terms—whether the speaker was a liar or truth-teller (or “good” or “evil”)—older adults’ memory for the source was the same as that of the younger adults.

The findings by Rahhal et al. (2002) are consistent with research showing that memory for emotional information, and particularly so for positive emotions, is preserved with age (Mather, Knight, & McCaffrey, 2005). According to Carstensen’s socioemotional selectivity theory (e.g., Carstensen, Isaacowitz, & Charles, 1999), older adults are likely to place emphasis on achieving emotional satisfaction and meaning through close social relationships. Recent studies suggest that as people age, they increasingly prefer persuasive messages with emotional rather than rational (Williams & Drolet, 2005) or knowledge-related appeals (Fung & Carstensen, 2003). Further, senior adults have better memory for messages with emotional than nonemotional content and are more likely than younger adults to be persuaded by messages with emotional content.

Work by Castel and Craik (2004) is consistent with the idea that information must be personally meaningful and relevant to the lives of older adults in order to be successfully remembered. They found that meaningful contexts support age-invariant memory ability, with intact recall of pricing information when prices reflected the market value but impaired memory when items were grossly over- or underpriced.

Because the elderly tend to engage in less self-initiated processing and rely heavily on environmental support, it is possible that they may be more influenced by contexts. This may argue for stability in the contexts in which information is presented and choices are made. Studies on expertise and personal relevance or meaningfulness of information are thus likely to continue to be important in distinguishing domains that draw on age-invariant memory abilities from those that rely on processes known to decline with aging. Such studies are needed as part of ongoing research efforts aimed at a systematic understanding of contextual factors leading to changes or stability of cognitive functioning with aging. Contextual factors that enable older adults to function particularly well may then lead to promising interventions and improvements in cognitive and behavioral outcomes.

Circadian arousal

A number of studies have found that the age differences in processing can be moderated by individual variation in circadian arousal patterns that is correlated with performance on a variety of cognitive tasks (e.g., May, Hasher, & Stoltzfus, 1993; Yoon, 1997). Specifically, performance tends to peak at certain level of circadian arousal when greater cognitive resources are presumably available, and this peak occurs, more or less regularly, at a specific point in the day. Hence, individual variation in circadian arousal patterns can significantly alter cognitive performance across time of day.

More directly relevant to the memory and aging is the finding that performance patterns across time of day are different for younger (typically university student participants) and older adults: younger adults’ performance tends to improve as the day progresses, whereas older adults’ performance peaks in the morning (during their optimal time of day) and then declines through the afternoon and evening (e.g., Adan, 1991; May et al., 1993). Normative data collected on over 2,200 college students (aged 18–23) and 1,200 older adults (aged 60–75) in North America indicate that roughly 40% of younger adults show eveningness tendencies, with less than 10% showing morningness tendencies. By contrast, less than 2% of older adults show eveningness tendencies, and the majority (~79%) are morning-types. Clearly, younger and older adults differ markedly in their circadian peaks over the day, and insofar as cognition follows circadian arousal patterns, the norms

suggest that performance of many younger adults will improve across the day, while that of most older adults will deteriorate as the day progresses.

As one example of dramatic time of day differences in how younger and older adults live their daily lives, consider age differences in media use and shopping (Yoon, 1997). More than 80% of the older participants in that study indicated that they read newspapers early in the morning, while only 14 % of younger subjects reported doing so during early morning hours. Magazines, on the other hand, were read in the afternoon or evening by more than two-thirds of both younger and older adults. About half of the older people indicated a clear preference for shopping in the morning or early afternoon, whereas younger people tended to prefer the late afternoon or evening. Older people's preference for shopping in the morning is consistent with their tendency to be mentally alert and energetic in the morning.

Other studies have found intellectual and physical behavior to vary across age and time of day. For example, prospective memory (remembering to do something in the future) involving older adults' medication and appointment adherence was significantly greater in the morning than in the afternoon or evening (Leirer, Tanke, & Morrow, 1994). By contrast, Skinner (1985) reported that college students' grades were significantly lower in morning classes than in afternoon and evening classes. Although these studies did not collect MEQ-type measures, they suggest real intellectual and behavioral differences across time of day that are quite consistent with circadian patterns reported for these age groups (see May et al., 1993; Yoon, 1997).

There is mounting evidence that in studies of age-related changes in memory, it is important to account for the match between an individual's peak circadian arousal period and the time at which testing occurs, an influence referred to as the "synchrony effect" (May et al., 1993). The synchrony between circadian arousal periods and performance can have a major impact on a wide array of cognitive tasks, particularly on those with an inhibitory component (for a review, see Yoon, May, Goldstein, & Hasher, in press). Yoon (1997) found that the elderly at their optimal time of day (i.e., morning) are able to engage in levels of detailed processing that are equivalent to those of younger adults at their optimal time of day for some types of messages. At their nonoptimal time of day, however, older adults show a marked decline in cognitive performance. This is in contrast to younger adults who are able to process in detail even at their nonoptimal time of day.

Yoon, Lee, and Danziger (2007) further investigated whether this time of day effect also impacts persuasion processes performed under relatively high involvement. They find that the attitudes of older adults are more strongly affected by an easy to process criterion, picture-relatedness, at their nonoptimal time of day (afternoon) and by a more difficult to process criterion, argument strength, at their optimal time of day (morning). In contrast, the attitudes of younger adults are affected primarily by argument strength at both their optimal (afternoon) and nonoptimal (morning) times of day. The results accentuate the need for matching marketing communications to the processing styles and abilities of older adults.

Taken together, the evidence suggests that in investigations of aging, it is important to guard against any potential biases by controlling for individual and group differences in circadian arousal patterns. Insofar as we know that older adults tend to reach their mental peak in the morning while younger adults do so in the evening, studies failing to account for such differences in arousal patterns may otherwise produce results that reflect a systematic under- or overestimation of relationships between age and other variables of interest.

The set of contextual factors that we have discussed thus far are by no means exhaustive. They are, however, intended to underscore the importance of research aimed at integrating memory in broader cognitive, biological, and social contexts in order to continue to enhance our understanding of older adults.

DECISION-MAKING AND PROBLEM-SOLVING

Models of Consumer Decision Making

Most models of consumer decision making identify at least two types of decision making. The first involves deliberative decision making with the classic five stages: problem recognition, information search, alternative evaluation, purchase decision, and post-purchase behavior. Such decision making typically reflects systematic attribute-by-attribute processing and is characterized as conscious, analytical, reason-based, and relatively slow.

In contrast, the second type of decision making is affective/experiential, and involves intuitive, automatic, associative, and fast decisions. When consumers have limited processing resources, they may pass directly from problem recognition to purchase decision to the post-purchase phase, using affective feeling to direct their choice process. So, for example, in one recent experiment, consumers with limited processing resources were more likely to choose chocolate cake, an option that generates positive affect and negative cognitions about health, than to choose fruit salad, an option that generates negative affect and positive cognitions about health (Shiv & Fedorikhin, 1999). In this type of decision making, ambient mood can also affect how consumers evaluate an object through a “how do I feel about it heuristic.” Consumers, using this heuristic, monitor their feelings to answer the question “how do I feel about it?” (Schwarz, 2001). They often end up mistaking their current mood state for their feeling toward a product (Pham, 1998).

Regarding age differences in use of deliberative and affective/experiential decision making, Hess, Rosenberg, and Waters (2001) have proposed a resource allocation hypothesis, which states that because older adults have limited cognitive resources, they tend to employ the latter affective/experiential information processing strategy in order to conserve their mental energy for important tasks. However, this hypothesis also suggests that older adults can, when necessary, employ deliberative information processing and decision making (a production deficiency). The frontal aging hypothesis, discussed earlier in the context of memory, suggests that age-related changes in frontal systems can favor affective/experiential type decision making (see Denburg, Tranel, & Bechara, 2005, for a discussion). This would tend to suggest that some older adults are unable to employ deliberative decision making (a processing deficiency).

A problem for consumer researchers has been defining what constitutes a good decision outcome. Some researchers have instructed consumers to use specific decision rules—generally the research indicates older adults are worse at applying specific decision rules (e.g., Cole & Gaeth, 1990). Other researchers have judged decision quality by focusing on satisfaction with choice. Research here reports that not only does satisfaction level vary with age (Cole & Balasubramanian, 1993), but also that the relationship between satisfaction and consumer decision making varies with age (Lambert-Pandraud, Laurent, & Lapersonne, 2005). Finally, decision speed and decision efficiency are also used to judge the quality of decision outcomes. Interestingly, some decision researchers have argued that by engaging the experiential processing system more and/or reducing the analytic processing needed, younger consumers can be aided to make better (quicker and more efficient) decisions, which are more similar to those of older adults (Hibbard & Peters, 2003).

Although consumer decision-making research spans a broad range of topics, researchers studying age differences in consumer decision making have tended to focus on just a few topic areas. In this section, we review the empirical evidence for age differences in search for information, evaluation of alternatives, purchase decisions, and post-purchase behavior.

Search for information

Older consumers often search in different places and for less information than younger consumers. For example, when making investment decisions, older consumers, compared to younger consum-

ers, are more likely to use television media and less likely to use the Internet for information about investments. In addition, older consumers spend less time searching for investment information than younger consumers (Lin & Lee, 2004). Similarly, a recent survey of automobile buyers found that older consumers searched for fewer brands, dealers, and models than younger consumers (Lambert-Pandraud, Laurent, & Lapersonne, 2005). Consistent findings have also been reported in the context of medical decisions (Ende, Kazis, Ash, & Moskowitz, 1989) and managerial decision making (Streufert, Pogash, Piaseck, & Post, 1990).

Another study investigated age differences in search behavior in a supermarket setting and in a computer laboratory (Cole & Balasubramanian, 1993). In the supermarket, shoppers inspected very few packages before making a choice, so no age differences emerged in how much people searched. However, when an observer intercepted shoppers and asked them to purchase a cereal that met certain nutritional criteria, younger adults engaged in more search than older adults who did not change how much they searched. In the laboratory, using a computer search program, older adults searched for less information about unfamiliar cereals than younger adults.

Whether or not age differences in search emerge, may depend on task characteristics. Age differences in search may not emerge when consumers perform simple, routine tasks such as grocery shopping because nobody searches very much in such situations. When engaging in familiar, but complex tasks, such as buying a new car, older adults may search less than younger adults because they use their years of shopping experience to design efficient search strategies. However, elderly consumers may restrict search when given a new search problem because of scarce information processing resources. For example, older consumers with diminished working memory capacity may not easily store information about alternatives in memory. As a result, they may not search for as much information as younger consumers.

Evaluation of alternatives and choice

There are three subissues explored here: (1) the types of information that people of different ages attend to, (2) how people of different ages combine information to form evaluations, and (3) whether or not there are systematic age differences in actual choices.

According to the socioemotional selectivity theory, age affects awareness of and use of emotional information (Carstensen et al., 1999). Older adults, who perceive their time horizon as limited, place greater emphasis on emotionally meaningful goals (goals related to feelings, such as balancing emotional states) than on knowledge-related goals (goals related to new information acquisitions). This age-related shift in goals could influence the type of information people use to make decisions (affective knowledge versus other types of information) (e.g., Fung & Carstensen, 2003).

Several researchers have suggested that older adults' extensive schema network, which have affective components tied to them, may allow them to easily use affective processing when making decisions (Myles-Worsley, Johnston, & Simons, 1988; Reyna, 2004). Investigators have found that adding affective category labels (poor, fair, good, excellent) alters age differences in decision making when participants are making choices about health plans (Peters, Slovic, & Hibbard, 2005). From a different perspective, a recent study examined framing effects in younger and older adults and found that when consumers used heuristic processing, older adults were more susceptible than younger adults to framing effects, but that the two groups did not differ when they were asked to justify their decisions or use more systematic processing (Kim, Goldstein, Hasher, & Zacks, 2005). This study also indicates that the types of information you present to consumers affects the size of age differences in decision making.

Regarding how people combine information, a recent study found that how people combined information to select a brand of financial services depended on both age and lifestyle variables (Lee & Marlowe, 2003). When selecting financial services, older singles were more likely to report

using a disjunctive decision strategy (e.g., I chose the financial institution that I rated really good on at least one thing) than other life stage groups, whereas retired older couples were most likely to report using conjunctive decision strategies (e.g., I chose the financial institution that I did not rate poorly on anything). Another study found that older adults were more likely than younger adults to adopt a strategy of eliminating alternatives as soon as possible (Riggle & Johnson, 1996).

Regarding choices, research points to a tendency for older adults to avoid making decisions by postponing or delegating them. In medical decision making, older adults are more likely than younger adults to indicate that they would leave the medical decisions up to the doctors instead of making them themselves (Steginga & Occhipinti, 2002). In other everyday decisions, older adults preferred avoidant strategies, but younger adults preferred problem focused action. Interestingly, however, as the emotional contents of the problems increased, younger adults' strategies became more like those of older adults (Blanchard-Fields, Camp, & Casper Jahnke, 1995).

Retail decisions and post-purchase behavior

A recent study of patronage motives for consumers in the selection of food and grocery stores found that those 55 and over differed from those under 55 on the importance they attached to variables such as store location, availability of age-related discounts, availability of personnel to assist consumers, availability of special services, and recommendations by other people their age (Moschis et al., 2004).

Some self-report studies indicate that elderly adults say they favor retailers that offer senior citizen discounts; but other surveys show that older adults are reluctant to participate in such programs. Tepper (1994) conducted an experiment with three older age subgroups in order to determine whether or not older adults respond favorably to age-related discounts. In the experiment, consumers learned that a 10% discount was either a senior citizen discount offered to customers over a certain age or a privileged customer discount offered to special customers. Consumers' reactions to the discount varied by age subgroup. Respondents in the youngest age group (50–54) were the least likely to use a discount promoted with an age segmentation cue, and adults over the age of 65 were willing to use either of the 10% discounts. The middle of the older age group (55–64) was willing to use the senior discount even though they believed that others would not give senior citizen discount users much respect.

Another study examined how older adults dispose of favorite possessions (Price, Arnould, & Curasi, 2000). Through in-depth interviews they studied various aspects of disposition decisions including precipitating events, emotions associated with decision, meaning of possessions, and tactics for disposing of possessions. Of these, precipitating events seemed most sensitive to age differences, but it would be informative to have future research that conducts age-based comparisons across different possession or consumption domains.

Heuristic/Affective Decision Making

Age difference in one type of affect-based decision making—risky choices—has been extensively studied in psychology (e.g., Denburg et al., 2005; Kovalchik, Camerer, Grether, Plott, & Allman, 2004). For example, Denburg et al. studied neurologically and psychiatrically healthy older adults and younger adults, using the Iowa Gambling Task, which entails a series of 100 card selections from four decks. A monetary gain follows some card selections, but a monetary loss follows others. The decks with lower immediate rewards have lower long-term punishments and thus yield an overall net gain, but decks with higher immediate reward have higher long-term punishment. Participants do not know about the reward/punishment schedules. A subset of the older group

manifested decision-making impairment on the gambling task, which Denburg et al. suggest may indicate impairment in the prefrontal region of the brain. Future research is needed linking performance on the gambling task to neurological changes.

Improving Consumer Decision Making

In general, the existing decision-making literature suggests that elderly consumers differ from younger consumers in important ways at each stage of the decision-making process. At the information search stage, the presence of age differences in the amount of search is not surprising because most of the consumer behavior research is based on extensive prior work in gerontology that suggests less search among older adults. At the alternative evaluation stage, a host of unresolved questions center on the decision rules and heuristics that different aged consumers use when evaluating alternatives. Some processes may differ across age groups because older consumers, with fewer cognitive resources than younger consumers, may perceive higher cognitive costs for certain strategies. Other processes may not differ, when consumers of all ages are able to use familiar and well-practiced heuristics.

We now discuss intervention programs such as decision aids, training programs and stimulus redesign.

Decision aids

A series of experiments used decision aids to reduce age differences in the correct use of the nutritional information contained on product labels (Cole & Gaeth, 1990). As discussed in the section on memory, older adults are known to be more susceptible to interference from the irrelevant components of a stimulus (or other environmental noise) than are younger adults. In the experiments, participants had to select a cereal that met certain criteria, but some participants first circled the relevant information before making a decision. Although both older and younger adults benefited from the simple aid, older consumers made fewer good nutritional choices than younger consumers. In a second experiment, the investigators put relevant information in a separate location on the label. This time, older adults with moderate, but not severe disembedding deficiencies, were helped, but the field independent younger individuals gained little from the aid. Given that the stated aim of nutritional labeling laws is to make nutritional information easy for all consumers to use, this study suggests that such information should be placed in the same spot on all labels.

In a different study, Cole and Balasubramanian (1993) tried to aid the use of nutritional information by encouraging older and younger adults to write information down as they acquired it from the computer. Using this decision aid, age differences in search intensity were greatly diminished.

Additional studies in the area of medicine suggest that by providing older adults with organizational charts and medication organizers, pharmacists can increase their patients' compliance with medication instructions (Park, Morell, Frieske, & Kincaid, 1992). Taken together, these studies suggest that decision aids may successfully improve consumer decision making. Circling, organizing, or writing down important information may especially help the elderly consumer focus on relevant information.

Training and education

Gaeth and Heath (1987) developed an interactive training program to reduce susceptibility to misleading advertising without increasing consumer suspicion of advertising claims. They found that

the training: (1) reduced susceptibility to misleading statements in both age groups, (2) equated misleadingness between older trained adults and younger untrained adults, and (3) reduced the younger adult's ability to discriminate between nonmisleading and potentially misleading claims. Regarding knowledge, older adults appear to build up a knowledge system that they can deploy to aid in decision making. Some argue that knowledge systems become increasingly selective and domain-specific with age, so that older adults can draw on this knowledge system to make better decisions. For example, Kovalchik et al. (2004) reported that older subjects did somewhat better than younger subjects on a 20-item trivia multiple choice test. More important from a decision-making perspective, however, older subjects in the study were better calibrated (knew better what they knew and did not know) than younger subjects. They may have learned through experience to temper their overconfidence and thus look more like experts. Future research is needed to address the circumstances when older adults can and cannot recruit their knowledge base for decision making.

Modifying stimuli

Hibbard and Peters (2003) suggest a number of interesting ways that stimuli could be modified to improve decision making of all ages, including providing cues about the goodness of information (e.g., labels, stars), and presenting information in the form of narratives or stories about someone else's experience. In one recently reported study on Medicare health plan choices, older consumers who received both information with cues about goodness and narratives in addition to basic data made better choices than consumers who only obtained basic data (Hibbard, 2002).

Another series of study have examined whether providing information in a manner consistent with adult schemas improves decision making about medication (Morrow, Leirer, Andrassy, Tanke, & Stine-Morrow, 1996). Nonadherence to prescribed medication, a widespread health care problem, is more common among elderly adults because the numbers of medications that people take often increases with age. These authors found that providing information in a schema consistent manner improved recall of information for both older and younger adults. Future research is needed to investigate whether schema consistent instruction improves adherence or quality of consumer decisions about medicine. It could well be that older adults are more prone to falsely remember information that is inaccurate or incorrect but otherwise consistent with their schemas.

Summary

In summary, efforts to eliminate age differences with decision aids have not been entirely successful in equating older adults' performance with that of younger adults. Instead, training, stimulus redesign, and decision aids often help all age groups.

To develop a decision aid that differentially benefits the older consumer, researchers must first deconstruct the consumer's task. They then need to identify exactly why and where in the substeps age differences emerge. Perhaps age differences emerge at the information acquisition stage because of working memory differences, but at the alternative evaluation stage they emerge because of differential attention to affective information. Once researchers understand the source of age differences, effective aids can be designed.

However, researchers need to evaluate the effects of decision aids on both targeted and nontargeted groups. For example, when researchers trained study participants to discriminate between directly asserted and implied claims, they increased younger participants' skepticism of advertising. Similarly, an advertiser targeting older adults may increase learning among this audience by

increasing the number of message repetitions. However, if younger adults also see the advertisements, the increased message repetitions may irritate them.

Additionally, the researchers need to think about designing a managerially relevant aid. For example, Cole and Gaeth (1990) suggested that older consumers highlight relevant information before making a decision. However, it is not practical to recommend that consumers take pens into the supermarket to highlight relevant information on product packages prior to purchase.

METHODOLOGICAL ISSUES IN AGING RESEARCH

The studies covered in this chapter are based primarily on experimental methods. Many compare well-educated healthy normal older adults (60+) with college undergraduates (18–22). Older adults' responses on many tasks are typically accompanied by greater variability than those of the relatively homogeneous college undergraduates.

The vast majority of experimental studies are based on cross-sectional designs. There are a handful of research labs that do collect longitudinal data (e.g., Seattle Longitudinal Study, Schaie, 2005; Berlin Aging Study, Baltes & Mayer, 1999). In addition, ICPSR (Inter-University Consortium for Political and Social Research) acts as a depository for a variety of longitudinal data sets primarily related to health and social status. Such data sets overcome some of the problems of cross-sectional design, but they are accompanied by their own unique problems such as sample selectivity and attrition.

In this section, we focus our discussion on issues that confront researchers conducting cross-sectional experimental studies on aging. First, recruiting older adults can be challenging compared to recruiting student participants. Researchers report difficulties finding sufficient numbers of older subjects to participate. Unlike younger college students, older adults, who are willing to participate in experimental studies, often must travel to the research laboratory and require substantially more compensation for their time. In addition, in cross-sectional research it is not possible to control for all the potential cohort differences. Nonetheless, researchers try to mitigate the effects of cohort differences by matching age groups in terms of health and educational status. However, even this matching can be problematic because quality of education varies between cohorts as does the length of time since education was completed. Most researchers screen participants for the ability to see and hear stimuli and administer vocabulary tests. Frequently, older adults score better on these vocabulary tests than college students.

In consumer studies, the stimuli may involve established brands or product categories, but because younger and older consumers often bring different product experience and knowledge to bear on consumer behavior, the stimuli may have different meaning to different age groups. Other variables are also hard to control for across age groups—e.g., a priori differences in motivation and arousal levels between younger and older study participants. Further, as discussed before, it may be important to control for synchrony effects; not doing so can systematically over-estimate or underestimate the extent of age-related differences.

As Schwarz (2003) points out, much of the elderly data are collected via retrospective behavioral reports, and hence, there are likely to be systematic biases in responses to the extent that older adults have to rely on processes that are age sensitive—e.g., retrieve relevant information from memory, form a judgment online, and report the judgment to the researcher. In addition, telephone interviews are likely to be more difficult for older adults than written surveys containing self-paced questions. Age differences may therefore magnify with elicitation methods that require more cognitive effort.

Finally, we note that in experimental studies of aging, external validity tends to be sacrificed in favor of internal validity, with convergence of insights occurring over time via conceptual replications. We suggest that richer insights about older adults in more natural consumer contexts are likely to emerge and complement findings from experiments through greater use of alternative qualitative research methods (e.g., observation, ethnography).

FUTURE RESEARCH DIRECTIONS AND CONCLUSIONS

Over the life course, consumers' strategies for solving different consumption problems evolve to reflect their changing life experiences and abilities. Not only do consumers face new problems (e.g., buying a color TV in the 1960s vs. buying a laptop computer in 2007), but they also experience physiological and cognitive changes. There are a number of unanswered questions about how older consumers adjust their decision-making strategies to changing cognitive abilities, social roles, and to task and context demands.

We hypothesize that situations where older consumers are likely to run into difficulties are typically unfamiliar situations involving new products or services. For example, some older adults may encounter difficulties learning information about the side effects of new prescription drugs through advertising; similarly, they may run into problems using the information found on the drug label. In other familiar situations, such as buying a car, older consumers may make better (more efficient and quicker) decisions than their younger counterparts.

The consumer behavior literature has contributed to knowledge by showing that age differences found in the laboratory research often emerge in "real" world settings (John & Cole, 1986). We identify several avenues for future research. One direction would be to examine how and when the older consumers' considerable knowledge and experience moderates any age differences that emerge in memory performance or decision making. In addition, because age-related changes in cognitive ability do not occur at the same rate for everyone (nor do they occur in everyone), there is considerable heterogeneity in the older market. For example, an individual's health history and life style may attenuate the timing and size of changes. So, another important direction for future research is to investigate differences within the elderly market.

A fruitful area for more research is analyses of consumer task characteristics that may exacerbate or minimize age differences. For example, much of the consumer behavior literature points out memory deficiencies in older adults in comparison with younger adults (see Williams & Drolet, 2005, for a notable exception). However, the magnitude of memory deficits appears to vary with the task conditions of information processing and how information is placed into or recovered from memory. Parallel to this task analysis would be the development and testing of decision aids, training and stimulus redesign that can make decision making easier for all consumers by reducing the cognitive effort required to execute a particular strategy.

In summary, we suggest that a better understanding of the changes associated with aging and how they interact with intra-individual and contextual factors will benefit multiple audiences, including consumers, public policy makers, and marketing managers. If we are to aid older adults to successfully meet the challenges of a rapidly changing and increasingly complex consumer environment, greater insights are needed regarding age differences in consumer behavior. Toward that end, we have in this chapter briefly discussed many of these differences, and have highlighted particularly important areas for future research.

III

MOTIVATION, AFFECT, AND CONSUMER DECISIONS

10

Positive Affect and Decision Processes

Some Recent Theoretical Developments With Practical Implications

ALICE M. ISEN

Cornell University

In recent years, in a growing number of fields, both basic and applied, there has been a great deal of interest in the influence of affect on thinking, problem solving, and decision making (see Gardner, 1985, and Isen, 1984a, 1984b, 2000, for overviews of some of the earlier work, and Cohen, Pham, & Andrade, chapter 11, this volume, for further review and interesting statistics on how work on affect has burgeoned). Much of the work on affect's influence on thinking and decision making has been of a basic or theoretical nature, but it has found ready application in diverse applied fields, from consumer behavior and management to medical decision making and diagnosis, from clinical work and coping research to applied economics and health policy. And, happily, research in the applied fields has contributed to the basic work in ways that only applied fields can do, adding their practical perspectives along with rigorous methods, to advance both the applications and the basic work itself substantially (e.g., Aspinwall, 1998; Aspinwall & Taylor, 1997; Boush & Loken, 1991; Feldman & Lynch, 1988; Folkes & Matta, 2004; Friestad & Wright, 1995; Keller, Lipkus, & Rimer, 2003; Lurie, 2004; Lynch, Marmorstein, & Weigold, 1988; Posavac, Sanbonmatsu, Kardes, & Fitzsimons, 2004; Roehm & Sternthal, 2001; Staw & Barsade, 1993; Taylor & Aspinwall, 1996; Tybout, Sternthal, Malaviya, Bakamitsos, & Park, 2005; Weiss, Nicholas, & Daus, 1999, to name just a few of the many potential examples of excellent work from applied fields that contributes back to theory).

A recent paper in the *Journal of Consumer Psychology* discussed some of the affect findings and their potential applications (Isen, 2001). The purpose of the present chapter is to report on some more recent developments in the study of positive affect's influence on thinking and decision making, with an eye toward laying the groundwork for integrating these new developments into the applied fields, particularly consumer behavior. As noted by Cohen et al. (chapter 11, this volume), research in the area of emotion has increased dramatically. Thus, I could not hope to include all of the new developments in emotion in this chapter, and what I will cover will be only a portion of the interesting topics relating to affect that are currently under investigation that hold promise for contributing further to the field of consumer psychology. The topics I will address include the following: Focus of attention ("broad" versus "narrow" or "global" and "local"); distractibility; false

memory; cognitive monitoring and the metacognition that follows from monitoring; and self-control. I have chosen these topics because, although there is growing activity relating to the effect of affect on those processes, and they are of clear potential importance to applied fields, the applied fields such as consumer behavior have not yet begun to investigate them extensively. Even within this circumscribed set of phenomena, space limitations preclude my conducting a complete review, as each one is a vast topic in itself. My goal in this chapter will be simply to point out some of the current work that is being done on these and related phenomena, work that has potential for contributing further to our understanding of the impact of positive affect on consumers' thought and decision processes.

FOCUS OF ATTENTION

Some of the recent theoretical developments regarding affect have centered on the question of the influence that affect has on focus of attention. I begin with a brief historical digression, for the purpose of providing context: Affect and focus of attention has been a question of interest for decades, but the form that it took historically was somewhat different from what is being investigated currently. For example, in the 1950s Easterbrook (1959) proposed that arousal or anxiety, called "emotion," narrowed the focus of attention and reduced cue utilization. That view was quite compatible with a line of thinking emerging from the decades preceding it that conceptualized high motivation or "Drive" (D) or arousal as reducing cue utilization (e.g., Bruner, Matter, & Papanek, 1955) and thus potentially interfering with performance. This interest itself stemmed from the even earlier suggestion that too high motivation or arousal—later to be thought of, often, as the emotion of anxiety—resulted in impaired performance (Yerkes & Dodson, 1908). In the early and middle part of the last century, scientific consideration was given to "arousal" as a factor in behavior, thinking or learning, and performance, but it was not entirely clear how arousal should be conceptualized. Based on theories prevalent at that time, it was demonstrated, primarily in animal learning studies, that arousal or high D (motivation) facilitated the dominant response in the organism's repertoire (see Hilgard & Bower, 1966, and Woodworth & Schlosberg, 1954, for consideration of the role of arousal or "Drive" in various theories of learning, of the time). This, then, later also fit with the idea that arousal ("emotion") would narrow focus and reduce cue utilization of peripheral or secondary cues as demonstrated by authors such as Bruner et al. (1955) and Easterbrook, (1959).

It seems that affect (emotion) and arousal were often thought to be synonymous, and co-mixed with motivation. At least one theorist held the position specifically that affect and arousal were synonymous and that there was no real role for emotion apart from motivation in the form of arousal (Duffy, 1934, 1941). Arousal was seen in most of these formulations as necessary to motivate behavior, but generally disruptive beyond the basic level needed to energize behavior (e.g., Yerkes & Dodson, 1908). Possibly as a result of this legacy, somewhat later views that included emotion as separate from arousal or motivation also tended to see it as disruptive (e.g., Simon, 1967). But none of these views, over all of those decades, considered emotion to be anything other than negative in tone, perhaps stemming from its earlier conceptualization as too-high arousal.

Gradually affect, arousal, and motivation have been distinguished and studied separately, although there continues to be some confusion among them. For example, in common usage, anxiety, a negative affective state, is sometimes labeled "arousal" (also called "stress"), and it is often assumed that high arousal is negative in feeling tone. There are models of emotion that distinguish between affect and arousal (see, e.g., Russell & Carroll, 1999; Watson & Tellegen, 1999, for discussions of these models), and some research has investigated valence and arousal separately (e.g., Lewinsohn & Mano, 1993; Mano, 1994; Sanbonmatsu & Kardes, 1988), or has

contrasted effects of positive affect, negative affect, and affectless arousal in the form of increased heart rate raised by physical movement such as stepping up and down (e.g., Isen & Daubman, 1984; Isen, Daubman, & Nowicki, 1987); but people still often slip into thinking of arousal as negative affect.

An important development in the past 30 years has been the recognition that positive and negative affect are separate phenomena, and that positive affect has clear and strong effects, often beneficial ones, on thinking and behavior—from generosity, helping, and social behavior, to problem solving, decision making, and basic cognitive processes (see, e.g., a review by Isen, 2004). Now that positive affect has been recognized as a process, or processes, of its own, with effects that are separate from those of arousal, negative affect, or motivation, the stage has been set for a fuller consideration of a range of influences of emotions on basic thought and behavioral processes.

In this context, the current work on affect and focus of attention builds on that earlier work that suggested that negative affect narrows the focus of attention, as was proposed by Easterbrook (1959) and others, but extends it now beyond negative emotion. More recently, people have begun looking at the effect that *positive* affect might have on focus of attention, with the idea that it might broaden the focus of attention. This was originally suggested based on an unexpected finding in a study of affect's influence on helping behavior (Isen, 1970; see Isen, 1990, for discussion). Participants were asked a set of questions about a person and activities that had unexpectedly occurred in the room where they were waiting for the experimenter to return. The results showed that not only did people in a negative affect condition (created by report of failure on a task) do more poorly on the surprise question about the surrounding conditions, but those in whom positive affect had been induced (by report of success on the task) did not have narrowed attention like people in the negative-affect condition, but reported more correct information about what had happened around them.

Effects of negative and positive affect compatible with those just described were reported more recently by Derryberry (1993), using a different task and materials. He found that success resulted in the ability to attend to low-value targets without missing high-value targets, whereas failure reduced the ability to attend to the low-value targets while attending to the high-value targets. Thus, it appears that positive affect (success) facilitates broader deployment of attention with no loss of accuracy or speed of processing, and negative affect (failure) reduces breadth of attention in order to remain accurate on a subset of the items. Derryberry (1993) summarizes the work on this effect as best described as showing that stressful states “narrow” focus rather than “concentrating” it, because they impair secondary information without facilitating primary information or causing improved performance on the primary items. With regard to positive affect, he concludes that attention may broaden but this broadening is not accompanied by dilution of resources devoted to the primary focus (p. 84).

More recently, other authors have begun to investigate the question of focus of attention (often referred to as “global” versus “local” processing) during positive and negative affect, looking at matters such as literally whether people first tend to use broad features of a display or more narrowly focused features to understand what they are seeing (e.g., Derryberry & Reed, 1998; Friedman & Forster, 2005; Gasper & Clore, 2002). For example, several studies use a task similar to the one developed by Navon (1977) or Kimchi & Palmer (1982), in which a stimulus is presented to participants that is a shape constructed out of smaller building blocks of another shape (for example, a square made out of smaller triangles), or one letter (say, F) made up of another letter (say, small Ls), with the stimulus thus being small Ls that form the shape of an F. In such studies people are asked, for example, to identify the shape or letter that is presented (responding “a square” or “F,” in the two examples above, would indicate a global focus, whereas saying “triangle” or “L” would indi-

cate local focus). According to Navon (1977) and Kimchi and Palmer (1982), most people respond based on the broader focus, indicating hierarchical organization of perception; but the point of the research on affect and focus has been to see whether positive and negative affect influence focus of attention, using that type of task. That research has reported that people in positive affect show a tendency to process the broader dimensions of the display, at least initially. Some researchers assume that this means that people in positive affect can *only* process broadly, that they cannot focus narrowly or would have difficulty, or show impaired processing and distractibility (more on this later), when required to focus narrowly.

A recent paper (Baumann & Kuhl, 2005) addressed this question specifically, using a task similar to one used in the research by Gasper and Clore (2002), by having the experimental participants solving a problem that required using the broader dimension and the narrower dimension in order to obtain the correct solution. The data in that paper show that people in positive affect were at least as capable of using the narrow focus if there was a reason to do so: When it was necessary for solving the problem, they opted for the narrow focus and performed well, as reflected by both reaction time and error rates (Baumann & Kuhl, 2005). This, then, supports the view that positive affect enables flexible deployment of attention (e.g., Isen, 2000a), rather than merely broadening attention or limiting people to the one, albeit broad, perspective. It is, thus, also compatible with the work reported by Derryberry (1993), described earlier, showing that positive affect leads to broader focus or perception (attention to secondary targets), but not at the cost of processing of valuable targets—that is, it leads to broader focus and success on low-value targets, but no dilution of resources devoted to the primary focus, and unimpaired success on high-value targets.

It must be noted that in the paper by Gasper and Clore (2002) what was actually found was that the positive-affect and the control condition did not differ, and that it was the negative-affect condition that was more narrowly focused than the controls. Although in places those authors were careful to state the difference between the positive and negative conditions in terms of negative affect causing a narrower focus, they did imply that their results indicate that positive mood fosters a global focus. Further, they again raise the points, made in more detail elsewhere, that positive affect is often assumed to prompt less extensive than usual thinking (which, they believe, would correspond to the more global focus), and that negative affect is often assumed to foster more extensive processing (which they argue would correspond to the more local focus). They acknowledge that their findings are not supportive of such views, in several ways; however, repetition of those contra-indicated views, after such acknowledgment, contributes to sustaining these misconceptions in the literature.

Thus, it is useful to consider the findings of other authors, such as those presented above—Baumann and Kuhl (2005) and Derryberry (1993), and others—to provide more context for the findings of Gasper and Clore (2002). As suggested by Derryberry and colleagues (e.g., Derryberry, 1993; Derryberry & Reed, 1998), narrow focus may not indicate more extensive processing, and the broad focus shown by the positive-feedback group in his studies corresponds to more, not less, extensive and effective processing.

Another program of research dealing with the question of focus, but in a different way, is that of Fredrickson, who postulates that people in positive affect “broaden and build” their skills, knowledge, and resources and then can use them in multiple ways, and describes upward spirals of well-being as resulting from positive feelings (e.g., Fredrickson, 1998; Fredrickson & Branigan, 2005). That is, not only do people in positive affect look at the bigger picture, but they build their resources as they do so. They look at the bigger picture not just literally or in perception, but they take in the context of a stimulus or event and learn about the whole stimulus or experience. This work would

be compatible with the interpretation, and findings described above, that people in positive affect are not *limited* to the wider perspective, even though they may be able to access it and use it more readily than those in comparison affect states.

THE FLEXIBILITY HYPOTHESIS

Fredrickson's view is also compatible with the flexibility hypothesis (e.g., Isen, 1984b, 1990, 2000a), which holds that people in positive affect are more flexible than others, and can see things both ways or change between broad and narrow focus, or typical and non-typical views, as appropriate in the situation. For example, in three studies investigating positive affect's influence on the unusualness, and range, of word associations to common, neutral words, it was found that people in positive affect did not lose the more common associates when they showed more unusual associates, and a broader range of first associates, to neutral words (Isen et al., 1985). Similarly, in two studies extending this work to investigate the influence of positive affect on the range of consumers' consideration sets (Kahn & Isen, 1993), people in the positive affect condition did not stop categorizing typical snacks as snacks, just because they broadened their consideration sets to include less typical foods in the snack category. Results compatible with these had also been reported in the categorization studies of Isen & Daubman (1984), which showed that, even though people in the positive-affect condition rated nontypical vehicles such as "camel" and "elevator" as better examples of the category "vehicle" than did controls, they still rated vehicles such as "car," "truck," and "bus" as better examples of the category than "elevator" and "camel" (and did not differ from controls in their ratings of the typical vehicles). Likewise, in studying categorization of social stimuli, Isen, Niedenthal, & Cantor (1992) reported that people in positive affect rated nontypical examples of the category "nurturant people" (e.g., bartender) as possible members of that category to a greater extent than did people in a control condition. At the same time, however, typical examples of the category such as "grandmother" were rated higher than the less typical exemplars by participants in both affect conditions, and to the same extent. Another set of studies that show flexibility in conjunction with positive affect are those reported by Murray, Sujan, Hirt, & Sujan (1990), who also found that people in positive affect showed more flexibility in categorizing stimuli.

Relating this flexibility to the topic of broad and narrow focus, this kind of flexibility is proposed to characterize people who are in a mild positive affective state, so that the fact that they may tend to look at the larger picture first, or broaden their view, or integrate context into their conceptualization, does not mean that they cannot focus or are limited to only the broad level of focus. Some of this work relates this ability, further, to a change in cognitive organization, wherein people are able to be flexible in the way they view and interpret situations and sets of stimuli, able to see and interpret them in multiple ways and reorganize and integrate their elements in multiple ways, often depending on the context or task that needs to be done (e.g., Isen, Daubman, & Nowicki, 1987; see, e.g., Isen, 1984b, 1993; Isen, Daubman, & Gorgoglione, 1987, for discussion). Thus, this view, compatibly with Fredrickson's and the results such as those reported above, suggests that people who are feeling happy not only have a broad perspective perceptually, but also have a broad perspective cognitively, can conceptualize and integrate more material and see it in more different ways (e.g., Isen, 1990, 1993a, 1993b). As we have seen, the evidence for this kind of increased flexibility has been obtained not only in the influence of positive affect on people's preference for variety, consideration sets in product choice, acceptance of unusual and nontypical associates to words and other stimuli, and ways of categorizing both social and non-social stimuli, but also in their problem-solving ability and innovation and creativity (e.g., Greene & Noice, 1988; Isen et al., 1987; Isen, 1993a;

Staw & Barsade, 1993). It has also been supported in work on coping, and in clinical and neuroscience studies of the influence of affect (e.g., Aspinwall, 1998; Compton, Wirtz, Pajoumand, Claus, & Heller, 2004; Taylor & Aspinwall, 1996; to name just a few).

Work on focus of attention has several potential applications to consumer behavior and understanding the decision processes of consumers. The consumer literature has started to investigate some of these topics, especially those stemming from the earlier work on flexibility in processing and categorization. For example, building on a similar line of thought—that positive affect may lead consumers to think more broadly about brands—consumer researchers have investigated the influence of affect on acceptability of brand extensions (e.g., Barone & Miniard, 2002; Barone, Miniard, & Romeo, 2000; Yeung & Wyer, 2005). One series of studies found that people in positive affect evaluated moderately incongruent extensions of favorably-evaluated brands, but not of unfavorably evaluated brands, as more acceptable than did controls (e.g., Barone & Miniard, 2002; Barone et al., 2000). Further exploration has addressed differences that may result when the affect in the situation arises not from extraneous sources but out of the brand itself (Yeung & Wyer, 2005).

ASYMMETRY OF EFFECTS ON POSITIVE AND NEGATIVE MATERIAL

The finding reported by Barone and Miniard (2002) of asymmetry in the effects of positive affect on positive stimuli and negative stimuli is an example of a phenomenon that has been found repeatedly in the affect literature and has very important implications for understanding the processes associated with positive affect. For example, although the term “mood congruency” seemed to catch on years ago, there was little support, from the very beginning, for the general, across-the-board idea of “mood congruency,” wherein any mood would be expected to cue material of the same affective tone and influence the evaluation of any material considered. In actuality, positive affect was found to be an effective cue for positive material, but negative affect, especially sadness, was not found to cue negative material or was found to do so to a much lesser extent than positive affect; similarly, the effect of positive affect on behavior such as helping and generosity was more clear than the effect of negative affect, which did not simply produce the opposite effects (see Isen, 1984b, 1990, for discussions).

More important and intriguing for the present discussion, however, is the fact that there were also asymmetries observed of the kind reported by Barone & Miniard (2002), wherein positive affect was found to have an impact on some kinds of stimuli but not others, or to operate in some situations but not others. For example, positive affect was found to influence the evaluation of neutral pictures but not positive or negative pictures, neutral facial expressions but not positive or negative facial expressions, and so on; and in terms of positive affect’s other kinds of effects, similarly, positive affect was demonstrated to influence the categorization of neutral-to-positive words, person types, and products, but not negative words, person types, or products (see, e.g., Isen, 1990, 2000, for discussion). Some of these findings have already been described above in greater detail.

These kinds of asymmetries indicate that there are different, and more complex, processes going on than mere mood-matching, or mood acting as a lens or filter, coloring everything rosy or making everything seem more similar and more acceptable. Rather, they suggest that affect’s influence depends on what the person is trying to accomplish and how the person interprets the situation, often in light of his or her goals. It is important to keep these kinds of findings in mind when considering the effects that are to be expected of positive affect.

Returning to consideration of the topic of the potential importance of positive affect’s influence on focus of attention, it seems, then, that the figurative effects of altered focus of attention have already begun to receive some attention in the field of consumer behavior. That work would

include studies stemming from the effects of affect on focus in the sense of flexibility (for example, broadening—or narrowing, when that is appropriate—in the use of categories in size or scope, reorganization of material, integration of context; and so forth). The research described above on affect's influence on reactions to brand extensions is an example of such work. Still, there remain many more potential applications to be addressed, such as integration of context and/or meaning, as well as further development of some that have been begun—as is evident from some of the most recent work on brand extension, for only one example.

Beyond that, however, the idea of focus of attention also has additional potential applications that might be fruitfully explored in consumer behavior, and the newer work focusing more directly on global versus local processing highlights some additional areas that may be useful to investigate. First, regardless of the fact that ultimately people in positive affect are flexible, not limited to the broad perspective, it is noteworthy that they may focus first on the broader picture or its implications and associates, or notice more about the entire setting of the presentation or notice peripheral aspects of displays or situations. Perhaps this is a figurative statement as well as a literal one, as has been discussed, and it is likely that people in positive affect may see multiple interpretations or applications of displays, products, companies, and/or what they discern are strategies by manufacturers. This suggests several lines of investigation as important consumer topics, drawing out both the figurative implications of broadened perspective and the literal. Practitioners and researchers trying to understand and accommodate to the preferred processing style of consumers who are in a positive affect state might benefit from knowing that people who are feeling mildly happy may notice more aspects of situations and displays, or that they may notice the broader, integrative ones first, or that they may integrate more thoughts and interpretations about an ad or a display or a product line, or that they may respond first to the implications or meaning of a display or ad or promotion experience. They may also integrate the context with the product more—which can result in a product's advantage, or disadvantage. These are just some of the potential applications of the current findings that would be intriguing topics for continued consumer research.

Although I am focusing on positive affect in this chapter, it seems appropriate to consider, in the context of focus of attention, the effect of negative affect or stress on attentional focus. This is because the findings relating negative affect and narrowed focus are so clear and strong and go back decades, if not a century. As reviewed above, here the evidence suggests clearly that stress causes people to focus in narrowly and to miss peripheral, global, or secondary aspects of situations or displays. Findings compatible with this statement have been obtained for decades, but the more recent ones are even more clear because they attempt to distinguish between arousal and affect and between negative and positive affect. In sum, regardless of how ideal it would be, especially for over-simplified versions of evolutionary accounts, if negative affect caused improved performance or had some direct, simple compensatory benefit associated with the limited range of focus that has been found to result from it, what has been found repeatedly in studies on the topic of affect-and-focus is that negative affect narrows focus (not “concentrates” it, as pointed out by Derryberry, 1993, for example) and limits what people attend to and how they interpret material.

Although marketers do not usually try to induce negative affect in consumers,¹ still there may be times when consumers will be in a negative state when shopping, or when considering ads or products. For example, when people are tired or in a hurry, or have to cope with tired, bored children who are with them, but still must shop or consider a purchase, and so forth, they may be stressed or in a negative state. Therefore, consumer researchers may find it of interest to investigate what kinds of displays or presentations would be most effective for such circumstances. One approach may be to try to make the consumer feel better, and perhaps this can be done with a broader display and playful peripheral, secondary material; however, one has to accept the possibility that the tired,

harassed shopper or ad viewer may miss the secondary material (and note that removing negative affect is a complex issue; see Isen, 1989, for discussion). Thus, another approach might be the time-honored, KIS (“Keep It Simple”). But these issues require research.

There are several implications to the various types of focus that have been described above, all of which require research to understand and implement correctly. First, there is the matter of actual focus—on the broader or more global stimulus or configuration of stimuli or materials that are present in a display. For only one example, marketers, especially when using positive-affect-inducing materials (e.g., ads, promotions, the products themselves) may want to use this knowledge to create displays they think might be favorable to their products, for example, with features they want to highlight portrayed more broadly or placed around the display in multiple locations to create the main theme so that they will be noticed first. The overall effect, or its implications, may be more important—especially initially—than the details. This would not be because people in positive affect are limited in their resources or motivation, nor because they cannot process the details, as has sometimes been suggested, but because they are taking in the whole picture, its context, and its meaning, and they may prefer experiencing more varied materials, materials with secondary themes as well as primary. However, before such strategies are implemented, additional research on the topic, using complex materials and settings would be called for.

Second, as has become evident from our consideration of the evidence here, the effect of positive affect is really one of attentional flexibility, not breadth per se, and therefore having secondary themes that can be discerned and integrated with the larger theme might be especially attractive to people who are feeling happy. In fact, one way to accommodate tired or time-pressed consumers at the same time as those who are enjoying the experience may be to have a simple focal message within a larger or broader context that offers the variety and secondary themes that may be attractive and can be selected and attended to by those who are in positive affect.

Third, the research reviewed suggests that people in positive affect may integrate disparate aspects of displays or products and see or construct more different meanings and applications of the materials or products. This possibility was actually discussed also in an earlier consideration of the effect of positive affect on cognitive organization (e.g., Isen, 1993a, 1993b), but now we know more about how such effects may occur and the factors that may influence them, and additional research on these topics could be very helpful.

DISTRACTIBILITY

As has been pointed out already in this chapter and elsewhere, it is well established that positive affect leads to flexibility in thinking and problem solving. This capability is evident in people’s ratings, choices, categorizations, word associations, innovation, problem solving, and other thought processes, measured in many different ways (see, e.g., Isen, 2000a, for illustration and discussion). A growing body of evidence suggests that this flexibility means that people can deploy their attention to multiple targets, can change attention, set, goals, or interpretation, can integrate ideas and use that integration to help solve problems, and so forth (e.g., Derryberry, 1993; Isen et al., 1987; see Isen, 2000a, for discussion). This increased flexibility does not mean that their thinking is “loose” or unhinged or wanders, or *must* move from topic to topic, but rather that they can deploy their attention to multiple targets or change set, when they choose to do so.

Nonetheless, some authors have reasoned that flexibility implies distractibility, as if attentional focus cannot be maintained, or is more difficult to maintain, in cases where flexibility is present (e.g., Dreisbach & Goschke, 2004). Thus, Dreisbach and Goschke (2004) have argued that people in positive affect will be less susceptible to perseveration (i.e., the inability to change set, focus, or

goal when the problem changes), but more susceptible to distraction (the inability to stay on target), because, they reason, there is a reciprocal relationship between perseveration and distractibility (e.g., Dreisbach & Goschke, 2004). In other words, they assume that an influence that leads people to be more flexible, and not constrained to keep thinking about or responding to the same stimulus in the same way, will also lead people to be more easily distracted or unable to stay on target; and they predict that this will be the case for people in positive affect. In its simplest form, the argument would be something like saying that, because positive affect increases flexibility, and broadens perspective and/or focus of attention, it will carry a benefit when people need to change focus, but a cost when people need to stay on target. Those authors present data showing that positive affect does decrease perseveration (decreases the tendency to stay on a given task or target or response set when it is no longer appropriate) but that it also does increase distractibility, in the form of reaction time (though not errors) on a target stimulus, when the distractor stimulus consists of items that were previously correct but no longer represent correct answers (a failure of what they call “learned irrelevance”), or when the distractor is novel. Their definition of distractibility, however, is not what one would expect—it is not the simple inability to stay on target or keep the same frame of reference—but rather bears a complex relationship to the nature of the interfering stimulus. (In some ways it even seems to be like perseveration, because it involves the “failure of learned irrelevance,” which would seem to imply a perseveration of the idea that the old stimulus is still relevant. However, those authors distinguish between perseveration and this kind of distractibility.)

Leaving that aside, the argument is an interesting one that raises several interesting issues, from whether those two processes (perseveration and distractibility) are reciprocally related, to whether additional processes (such as inhibition, cognitive monitoring, or other response factors) might not come into play to moderate the ultimate outcome, and need to be added to the mix in order to understand the role that affect will play in attentive processes. In fact, other authors have reported data that would not support Dreisbach and Goschke’s (2004) interpretation of their data. For example, if one relates Dreisbach and Goschke’s (2004) reasoning to the findings on focus of attention, described earlier, the argument would be that a broader focus of attention and ability to monitor secondary targets would imply an inability to stay on target and perform as well on the main targets. But, as discussed above, this is not what was found by, for example, Derryberry (1993). Rather, what was found was that positive affect led people to be able to perform well on secondary targets while at the same time showing no diminution in performance on the main targets.

In addition, other authors have also found results that suggest that more is going on than a simple reciprocal relationship between flexibility and distractibility. For example, Kuhl and Kazen (1999) studied the influence of positive affect on Stroop interference. The Stroop task is one in which a person is shown a stimulus that consists of a word that is the name of a color, but the word is written in a different color ink; and the person’s task is to report the color of the ink in which the word is written. Therefore, in that task, two conflicting tendencies are activated, the tendency to report the color that the word is written in, and the tendency to read the word, which is the name of a different color (and which would produce an incorrect response). In order to respond correctly, the person must suppress the tendency to read the word, which is the dominant response, and which would produce the wrong answer. Reaction times to giving the correct response are measured in order to gauge amount of interference, called “Stroop interference,” arising from that dominant tendency. Kuhl and Kazen (1999) reported that positive affect improves performance (reaction time) on this task and removes Stroop interference. Another program of research, by Friedman and Forster (e.g., 2005), also reports, compatibly with this work, that approach motivation—a concept that may relate to positive affect (see Carver, Sutton, & Scheier, 2000)—improves performance on the Stroop task and facilitates attentional flexibility.

Another recent series of three studies also finds that positive affect induced in two additional ways (receipt of a small bag of 10 wrapped hard candies, and viewing a few minutes of a non-sexual, non-aggressive amusing film) leads people to perform better on tasks requiring divided attention or incidental learning, while not impairing performance on the main task (Isen & Shmidt, 2007). This held true whether the potentially interfering stimuli were novel or previously correct (now incorrect) responses.

The results reported by Kuhl and Kazen (1999) and Kazen and Kuhl (2005), and other authors, indicate that positive affect facilitates the processes that underlie improved performance on tasks such as the Stroop task—which include maintaining a difficult intention and inhibiting an unwanted response. This means that with positive affect, a difficult intention can be carried out, in the presence of an otherwise dominant response, with less increase in reaction time than is observed in the control group. This suggests that, when the context of the whole task is taken into account, positive affect, rather than causing distractibility, enables control. The authors' interpretation of their finding included the point that positive affect facilitates the processes that allow the correct (intended) process to be activated, when two processes are in competition, and then to be performed at the appropriate time. Thus, in tasks involving distraction and perseveration, it seems that processes of inhibition, activation, maintenance, monitoring, and intention must also be considered.

To summarize this matter, then, the evidence with regard to positive affect's influence on distractibility is mixed: Some evidence suggests that positive affect, while decreasing perseveration, may increase distractibility, as measured by reaction time to irrelevant stimuli that previously were relevant. But there is also countervailing evidence suggesting that positive affect allows deployment of attention to additional targets without interfering with performance on the primary targets. And there is also evidence suggesting that positive affect, compared with a control condition, removes Stroop interference, which indicates that people in positive affect are better than controls at maintaining a difficult intention and inhibiting unwanted responses. More research is needed on this topic, but it is an area that relates to what is called "executive" attention or processing, and the topic of affect's influence on executive processing is the focus of much current research.

Similarly, this seems to be an issue that could be of substantial interest to consumer researchers and seems worth pursuing in a consumer context. Not only would it be important for consumer researchers to know whether positive affect increases distractibility, and if so how that plays out in a complex consumer context, but this seems to be one of those situations in which the rich stimulus context provided by realistic consumer tasks, stimuli, and settings might add to the theoretical understanding of the fundamental issue, as well.

That is, it may be that in the abstract, or with a tedious task or meaningless distinction between two barely distinguishable stimuli, people in positive affect may appear to be distractible, because they may take a few additional milliseconds to respond (however, the contradictory evidence reported by other authors should also be kept in mind). But in such a setting one cannot know the reason for the person's increased response time—were they unable to respond more quickly, or did they take a few milliseconds to think about something more interesting, because they didn't think it would matter? While it may be possible to argue that something like this is the meaning of "distractible," it seems more likely that such a context-induced effect would not be what most people would mean when they say that a person is distractible. (Distractibility might more usually be thought of as akin to impulsiveness or failure to inhibit response to the distracting stimulus—in fact, Dreisbach & Goschke, 2004, make this connection.) Further, motivational differences between affect and control conditions may exist in such a context. We do know that people in positive affect are more likely to do what they prefer to do (e.g., see Isen & Reeve, 2005, for discussion),

and the apparent “distractibility” could simply be a reflection of that greater freedom to behave as one wishes or this alternative motive that is introduced by positive affect in that context.

Still, the more general point to be made is that the question of whether positive affect influences distractibility seems an important topic for investigation. In addition, given several of the findings that have been discussed thus far, one might also ask whether negative affect influences distractibility. To progress, some agreement will have to be achieved on the best way to define and measure distractibility, and distinctions among the existing ways should be considered (perhaps some ways are more appropriate for certain purposes, whereas other ways will be more appropriate for others). In addition, the question of whether distractibility involves impulsiveness also needs to be considered. Most likely distinctions will need to be drawn here, especially given the findings in the affect-and-risk literature, which call into question the idea that people in positive affect are careless, impulsive risk-takers (see, e.g., Isen, 2000b, for discussion), and also question the assumption that people in negative affect are careful in risky situations. Finally, distinctions among stimuli and settings may need to be considered as well, in coming to predictions about how distractible people in various affective states will be. All of this suggests that consumer research on the topic would be welcome and needed.

FALSE MEMORY

Another current line of investigation that follows from one possible extrapolation of the affect-flexibility link is the proposition that positive affect will lead to false memory. False memory has been studied using what is called the Deese-Roediger-McDermott (DRM) paradigm (Deese, 1959; Roediger & McDermott, 1995). In this procedure, participants are presented with multiple lists of semantically associated words (e.g., “snow,” “winter,” “ice,” and so on) that are related also to a critical item (e.g., “cold”) that is not presented. Then they are given a recognition test, that presents words that were previously presented and words that were not previously presented, including the critical word (the one that is related to the theme of the presented words but was not itself presented), and asks participants to say whether each word in the test was presented before or not. The test for “false memory” is whether the critical word is erroneously identified as having been presented previously. Results in the cognitive psychology literature indicate that false memory measured in this way is very common, with people generally making this error as frequently as they correctly identify words that had been presented (see Roediger, McDermott, & Robinson, 1998, for review).

It has been reported that positive affect leads to better recall of schematic material—that is, material that is related to a given schema or theme (e.g., Bless et al., 1996). Thus, in a recent paper, Storbeck and Clore (2005) used a procedure based on the DRM paradigm (not exactly following the DRM paradigm, a difference that will be discussed later), and proposed that positive affect would lead to an increase in false memory. Those authors apparently reasoned that because people in positive affect could think of more related words than controls, or perhaps because they would just be more likely to think of related words than controls would, people in positive affect would also have a greater rate of false memory. However, that is not what happened.

The title of the article by Storbeck and Clore (2005) (“With sadness comes accuracy, with happiness, false memory”) suggests that positive affect does lead to more false memory, but in actuality, what those authors found was that positive affect did not increase false memory above the level of the control group. They also had a negative-affect group in their study, and they reported a difference between the negative-affect group on the one hand, and the control group and positive affect group on the other, with the latter two not differing from each other, and the negative-affect group lower than both of the comparison groups. Thus, it seems that the effect of positive affect on false memory

was not obtained, but it also seems that an interesting effect of negative affect may have been obtained, because negative affect appeared to reduce false memory compared with the control group.

However, it is not clear that the effect of negative affect was actually an effect on false memory. To understand these results fully, it should be noted that Storbeck and Clore (2005) did not use a recognition test to assess false memory, but rather instructed participants to indicate all of the thoughts they had during the presentation of the initial word list, including any related thoughts. Thus, they used a procedure that simply asked people to indicate all of the thoughts they had, and did not allow or request any role for monitoring or checking. That is, if people usually monitor and check their thoughts and answers to questions about what had been presented previously and what had not, or if they could do so if requested to do so, or if alerted to the need to do so in order to avoid errors, and if monitoring and checking play a crucial role in whether or not false memory occurs, when people are asked to distinguish between words that had been presented and those that had not been presented, the effect of any such process would not be apparent using the procedure used by Storbeck and Clore (2005). That is, if there is more to false memory than just having associates to presented words, then false memory would not be assessed by the technique used by Storbeck and Clore (2005).

In fact, it would seem that false memory involves not just associated words coming to mind, but also a failure of monitoring, a failure to differentiate between words that come to mind and words that were previously presented. For a person to have a false memory, he or she must fail to realize that the word that came to mind was not a previously presented word, and the person must incorrectly report that the word had been presented previously. Therefore, the occurrence of false memory depends, not just on having associated or schematically related thoughts and words to the presented words, but also on a failure of monitoring so as not to be able to know that those words were not previously presented. Perhaps having more associates to a given idea or event may indeed play a role, as hypothesized by Storbeck and Clore (2005), but it would seem important also to assess the critical process of monitoring as well, in order to determine whether false memory should occur.

Further, if there is reason to believe that affect differentially influences monitoring or checking, and in particular that positive affect improves or increases the tendency to engage in such monitoring processes, then it is apparent that any such beneficial influence would be obscured in the research by Storbeck and Clore (2005). In fact, there is evidence in the literature that positive affect does facilitate monitoring and checking. Although some researchers have argued that positive affect leads to superficial or sloppy or impulsive processing, there is a great deal of evidence in the affect-and-problem-solving literature, the affect-and-risk literature, and other studies of positive affect, that points to careful, thorough thinking by people in positive affect (see Isen, 2000a, for review and discussion of this issue).

Compatibly with this suggestion, increased monitoring and decreased false memory were indeed found in a recent pair of studies investigating the influence of positive affect on false memory using the DRM paradigm including a recognition test (Yang, Ceci, & Isen, 2006). In these studies, in Study 1, it was found, again, that the positive affect and control conditions did not differ in false memory, but in Study 2, in which participants were told about the nature of the false-memory effect and encouraged not to fall prey to such errors, people in the positive-affect condition showed significantly less false memory than controls. The authors attributed this effect to better monitoring on the part of the positive-affect participants.

This finding, indicating that people in positive affect are more likely to engage in monitoring or checking of their thinking or behavior, is quite compatible with many other findings in the affect literature. For example, one study that illustrates this greater tendency to check was conducted in a

medical setting and involved physicians asked to make a diagnosis of a hypothetical patient. Those in the positive-affect condition, even though they were quicker to make a connection between the relevant disease area and the described symptoms, were also more likely than those in the control condition to stay open to the possibility that their initial hypothesis might be wrong, and to check their answers and hypotheses against additional information before giving a final answer to the diagnostic problem (Estrada, Isen, & Young, 1997). A similar finding was obtained in a study of fourth-year medical students who were asked to solve a problem that involved identifying which of several hypothetical patients was most likely to have a certain disease, given various sets of signs and symptoms. In that study, the clinicians in the positive affect condition, even though they came up with the correct answer earlier in their protocols, did not stop working with the materials and were significantly more likely than controls to go beyond the assigned task and do more, checking on the rest of the cases to make sure that each was not likely to have the target disease (see Isen, 2000a, for discussion).

As a final example of this tendency, consider the effects that have been observed in the affect-and-risk literature. There, it has been found repeatedly that people in whom positive affect is induced, and who are facing the possibility of a real and meaningful loss, display more caution and are risk-averse compared with controls—are significantly less likely than those in control groups to bet, or bet significantly less. In one of those studies that included a thought-listing task, it was also found, specifically, that participants in the positive-affect group listed more thoughts about the potential loss, which relates to increased checking and monitoring and may help to explain their increased caution (Isen & Geva, 1987).

False memory, especially as it has been defined in the research literature, actually involves confusion among stimuli that are thematically related. This is a topic that would naturally be of interest to researchers and practitioners in consumer psychology. Confusion among brands, product categories, product attributes, product benefits, advertisements, manufacturers, and the like is a serious potential problem in marketing and in every phase of dealing with consumers. As noted, in the psychology literature, it has been demonstrated that false memory is quite prevalent in general, indicating that it may be a problem wherever people want to induce the ability to differentiate among items or reasons or concepts of any kind. It is a problem in marketing, just as it is a general problem—perhaps even more-so, because marketing is concerned with persuasion and presentation and differentiation of options. Therefore, if research suggests something that could reduce the effects of the false-memory process, that would be important to investigate further.

Especially if there is reason to believe that affect can make false memory more likely, or less likely—or if it would be possible to determine circumstances under which each of these possibilities is likely to be true—this would be very useful to study in a consumer context. Even more important, research suggesting that positive affect can reduce false memory would be crucial to pursue—in part because marketing and product presentation depend heavily on developing positive affect among one's customers. And at the same time, differentiation of one's product is a constant concern and goal. Thus, this phenomenon might be investigated in the context of marketing stimuli, using products and brands or attributes or benefits, and so on, instead of just neutral, common words. Beyond that, studies might focus on ways to develop strategies to overcome this ubiquitous problem. (If it does turn out that negative affect reduces false memory—which is not yet clear—still it might not be wise to adopt a strategy of putting consumers into negative affect for that purpose.)

One caveat should be raised, before leaving this topic, and that has to do with the factors that would lead someone to monitor carefully, and specifically the factors that might lead someone in a mild positive affective state to monitor carefully. In the study reported by Yang et al., 2006, it was

found that people in positive affect did monitor more carefully than controls, when participants were told about the phenomenon of possible intrusions of schematically related words. It had been found previously that people generally show substantially reduced error rates when given such warnings and encouragement to avoid those kinds of errors (e.g., Gallo, Roediger, & McDermott, 2001; McCabe & Anderson, 2002). And the study by Yang et al., 2006, found that this is even more true among people who were feeling mildly happy. Still one might wonder whether people will make the effort to monitor carefully in an everyday consumer situation (shopping, reading or viewing ads, seeing promotional material, and so forth), especially if the product is a low-involvement product, or the situation is one in which people might not want to put forth the effort to distinguish among ads or features or brands, or any kind of stimulus materials shown to them. And one might wonder, equally, whether the advantage of people in positive affect in monitoring and distinguishing among stimuli would be obtained in settings related to purchases.

Of course, different kinds of purchases may evoke different strategies and willingness to exert effort. For some kinds of purchases consumers may be willing to put forth a lot of effort to understand the purchase landscape; and there perhaps one would see the advantage to people in positive affect that was observed in the work by Yang et al., 2006. Or there may be factors in the way the message or product or promotion is presented that can lead consumers to be willing to differentiate or monitor differences, for example, among products or features of products. These are primarily empirical questions, and ones that would be exciting research topics in consumer behavior.

COGNITIVE MONITORING AND METACOGNITION

The work on false memory, showing that positive affect reduces false memory when people are warned that such intrusion effects often occur, calls attention to the role of fundamental cognitive processes such as encoding strategies, cognitive monitoring, and metacognition (i.e., awareness of one's own knowledge or lack of it) in people's processing of information.² However, even more interestingly, that work also implicates positive affect as a factor in these processes of monitoring and metacognition—and it suggests that people can exert control over such fundamental processes that determine many aspects of thinking and functioning. In the recent studies by Yang et al. (2006), it was reported that people in positive affect had a more correct sense of whether a word had actually been presented or just “felt” like it had been presented (“remember” versus “know” judgments), which is often related to metacognition (see, Nelson, 1996, for discussion of this and related topics). In the second study, importantly, people in the positive affect condition took better advantage of a warning about the possibility of intrusions arising from conceptually related material, possibly indicating improved monitoring of their knowledge.

Similarly, several studies of problem solving and decision making have shown that people in positive affect are more careful and controlled in the way they go about thinking about a problem: they tend to elaborate on ideas and stimulus materials presented and have more thoughts about them, check more, remain open to alternative hypotheses, decline to bet, or bet less, in a risky, real gambling situation, have more thoughts about potential dangers in a dangerous situation, and so forth (e.g., Estrada et al., 1997; Isen, Daubman, & Nowicki, 1987; Isen & Geva, 1987; Isen et al., 1991; see Isen, 2000a for discussion).

Thus, it may be instructive to investigate this question specifically, and especially in a consumer context. These findings relating to monitoring have not yet been fully developed or extensively researched in the context of affect's influence or contribution to them, but the topic area would seem to provide a set of possibilities for research that consumer researchers might find especially interesting.

THE DOPAMINE HYPOTHESIS

These findings and suggestions regarding monitoring and metacognition are also compatible with the dopamine hypothesis regarding positive affect's influence on cognitive processes, which is a theory that can help in understanding positive affect's facilitative effect on thinking processes (e.g., Isen, 2000a). It has been proposed that positive affect is associated with release of brain dopamine, which activates regions of the brain such as frontal areas that are known to be related to thinking, working memory, attentional flexibility, and other related cognitive processes (Ashby, Isen, & Turken, 1999). The growing body of work on social cognitive neuroscience is beyond the scope of this chapter; however, it is important to mention at least the dopamine hypothesis in the context of these ideas about positive affect's improving processes such as monitoring. Activation of frontal brain regions may account for participants' improved ability to consider multiple factors in the situation, including long-term welfare and not just immediate pleasant feelings, ability to monitor and keep track of several factors in the situation at the same time, and other indications of more complex cognitive processing. Despite the fact that space limitations preclude discussion of the social cognitive neuroscience area, this is surely an area that would be an exciting addition to the consumer research literature.

The findings regarding metacognition and monitoring may relate to matters of self-control, as well. Self-control is usually assumed to relate to refraining from some tempting action, such as eating rich food when one is trying to limit indulgence in such consumption, or lashing out in anger (note) at someone who has been offensive, and it is often studied in such a context—refraining from some action. It can also be conceptualized as relating to staying at a task that is difficult or unpleasant or competing with some more attractive task—staying at work studying when a friend calls and suggests going to a movie, for example. But self-control can also involve keeping one's mental focus, organizing cognitive material according to a strategy for remembering it or working with it, monitoring the occurrence of intruding but misleading cognitions, checking to make sure that one is staying on target or on task. Thus, the processes of metacognition and/or monitoring and checking may relate to self-control of a kind. Even though this kind of self-control may be seen as different from prototypic resistance to temptation, still it is possible to see the similarities and connections. Thus, based on the kinds of findings discussed above in the literature on focus, false memory, intention, intention-memory (e.g., Kuhl & Kazen, 1999), and the like, there may also be reason to expect a link between positive affect and self-control (and between some kinds of negative affect and lack of self-control), based on processes such as monitoring.

SELF-CONTROL

Self-control is a topic that has always been of interest, at least indirectly, among researchers in consumer psychology, and similarly there has been a huge amount of research on self-control in the theoretical literature. A review of either of these bodies of research is beyond the scope of this chapter, but what I want to focus on in this section are two kinds of relatively recent lines of work on self-control that may provide additional opportunities for interesting consumer research, especially when integrated with work on affect. These involve self-regulation (including affect-regulation), and motivation, including the processes by which affect influences motivation.

The work described throughout this chapter—on affect's influence on flexibility in focus of attention, distractibility, false memory, meta-memory, and monitoring processes—also has implications for the influence of affect on self-control, at least one type of self-control. Take, for example, the findings reported with regard to false memory. As we have seen, they indicate that people in positive affect may have better monitoring functions and better meta-memory or awareness of their

own memory or thought processes (Yang et al., 2006). But, as noted above, in addition, those results also suggest that people in positive affect may have more self-control, because they were more successful at making use of the information that intrusions were likely in the situation, and they were better at refraining from falling prey to misleading intrusions. That is, the literature indicates, and the study by Yang et al. (2006) confirmed again, that error rates in general go down substantially when people are warned about the possibility of intrusions—indicating that people can monitor and decrease their likelihood of error in that situation. However, that study showed that people in positive affect benefited more than controls from having been made aware of that potential for errors. This suggests that people in the positive-affect group are better able to exert the control over their thought processes that enables them to keep straight which words were seen previously and which were not. (It should be noted that other aspects of the results reported by Yang et al., 2006, indicate that this effect cannot be attributed to increased motivation in the form of simply trying harder, because the conditions did not differ in overall levels of correct recognition.) The idea that monitoring ability is crucial to self-control is compatible with Carver's (e.g., 2004) model of the self-regulation process, though perhaps in a slightly different way.

Two programs of research that have stimulated a great deal of work focusing on self-regulation have been that of Baumeister, Tice, Vohs, and their colleagues (e.g., Baumeister et al., 1998), and that of Carver and Scheier and their colleagues (e.g., Carver, 2004; Carver & Scheier, 1998). The work of Baumeister and colleagues has centered on the idea that exerting self-control causes depletion of what is thought to be a limited self-control resource and therefore makes continued self-control, even in unrelated domains, less likely (if not impossible). The work of Carver and colleagues also relates to self-regulation, but takes a different focus, proposing a model involving a discrepancy-reducing feedback process that implicates resource monitoring in the process of control of both behavior and affect.

Of course, these descriptions of these two extensive lines of research are over-simplifications, but they serve to highlight two relatively new foci for a topic that has long been of interest in consumer behavior. Additional work relating these conceptualizations and lines of investigation to the consumer research area would be of substantial interest. In fact, some research in the consumer literature on these and related topics is already under way (e.g., Wan, Isen, & Sternthal, 2006; Wan & Sternthal, 2005). It is also interesting that Baumeister has directed some of his work recently to the consumer research domain (Baumeister, 2002).

Other lines of work on self-control, and particularly affect and self-control also offer promise of interesting development by consumer researchers. For example, Trope's model of "mood as a resource" suggests that positive affect increases the resources available to a person, and the additional resource enables a person to take a more future-oriented view or to consider his or her long-term welfare rather than simply opting for immediate affect maintenance (e.g., Gervy, Igou, & Trope, 2005; Trope & Pomerantz, 1998). In a recent paper, Raghunathan and Trope (2002) suggested a way to differentiate among three kinds of effects of positive affect that have been observed in the literature: affect as information (indicating whether it is important to process carefully), affect as a goal (i.e., affect-maintenance), and positive affect as providing additional resources that can be used during decision making or problem solving (e.g., Raghunathan & Trope, 2002). The authors suggest conditions under which each kind of effect might be expected. This differentiation suggests some interesting topics for continued research. It would also be important, however, to investigate the source and nature of the additional resources that affect provides.

Other authors have also emphasized that positive affect fosters taking one's long-term welfare into account rather than focusing only on immediate affect-maintenance (e.g., Aspinwall, 1998; Aspinwall & Brunhart, 1996; Aspinwall & Taylor, 1997; Isen & Geva, 1997; Isen & Reeve, 2005;

Reed & Aspinwall, 1998; Staw & Barsade, 1993; see also, Isen, 1993a, 1993b, 2000b, for discussion). They take the view that the broader perspective, greater flexibility, and capacity for utilizing and integrating more information, which is promoted by positive affect and positive states such as optimism or positive affectivity, enables the ability to take the long-term view or to realize what is most important in the situation (see, e.g., Isen, 2000a, 2007, for discussion). In other words, the flexibility fostered by positive affect enables the person to see several options, short-term and long-term, several aspects of situations, and to integrate them in deciding what to do. As discussed in this chapter, a substantial body of work supports the idea that positive affect promotes flexibility, the tendency to integrate more material and aspects of situations into decisions, to monitor situations more carefully, and so forth. Thus, those cognitive processes that are fostered by positive affect are the kind that contribute to the likelihood that the person will base his or her actions and decisions on a fuller consideration of the situation, including longer-term welfare where that is relevant.

These views are also compatible with the dopamine hypothesis regarding positive affect's influence on cognitive processes, mentioned in the previous section. As noted there, release of dopamine into frontal brain regions that foster processes that allow cognitive flexibility and complex cognitive processes, including working memory, monitoring processes, attentional flexibility, and the like, may play a role in positive affect's facilitation of complex cognitive processing. It thus may well play a role in enabling people to take their long-term welfare into account, as they think about more factors of many kinds in the situation (e.g., see Isen, 2000a). It may also be useful to consider the dopamine hypothesis in the context of any theories or models that propose that positive affect provides additional resources, because activation of brain areas that enable careful and effective thinking might well feel as though one had acquired additional resources, and it could account for participants' improved ability to consider multiple factors in the situation, including long-term welfare and not just immediate pleasant feelings.

The context of these theories about the role of flexibility and/or additional resources suggests the point that it is important to recognize that positive affect undoubtedly fosters more than one process at a time, and researchers need to take several of these into account at once when making predictions about what effect positive affect will have. It is especially important to take affect's influence on flexibility into account in making any prediction involving positive affect.

A problem has resulted from not taking this complexity into account, and unfortunately it has led to confusion in the literature on the effects of affect on cognitive processing. For example, starting with the proposition that positive affect, for example, has been found to have a certain effect, say, cueing positive material, or desire to maintain a positive state, some researchers have then assumed that this one effect drives the situation and can be followed to its logical conclusion in isolation from the rest of the factors in the situation and, importantly, in isolation from the other effects that are known to result from positive affect (most notably, flexibility). The reasoning in the research article might be something like the following: Positive affect cues positive material; therefore, if affect will play a role in the situation under consideration, it will be to trigger improved evaluations, and therefore everything will be more highly evaluated. As discussed earlier, the data have shown repeatedly that that is not the case. Negative or dangerous events or materials are not evaluated more favorably when one is feeling happy; no simple, blind bias or rosy filter appears.

Or another example might be to assume that because positive affect has been shown to engender a tendency to preserve the positive state, that people who are feeling happy will engage in affect-maintenance above all else (as some authors have caricatured the findings) and not consider negative material, even when that would be beneficial and informative for them. Over the years, again, the data have shown us that positive affect does not exert such a simple influence or produce such narrow effects (see, e.g., Isen, 1993b, 2000a, 2007, for discussion). Thus, an important proposition

to keep in mind when dealing with affect and trying to understand or predict its effects, is that the several effects of an affective state must be considered simultaneously and as an integrated whole, rather than developing hypotheses based on only one effect at a time.

Another point that needs to be made in this context is the general one that applies to most common situations, and that is that behavior is multi-determined: There is not just one motive operating at a time.³ This principle is not just applicable to situations involving affect, but is a constant in understanding people's experience, choices, and behavior. Thus, it is not only in situations of positive affect, but in all normal life situations, that researchers must be mindful of multiple motives influencing people at the same time. The work demonstrating that certain motives, such as affect maintenance, are active during a positive-affect state only serve to help delineate some of the motives that are likely to be present and that may be exerting an influence. The identification that a certain specific one is likely to be more active during a given state, such as positive affect, does not mean that that motive will be the only one or even the most dominant one. Other cognitive factors will play a role, as noted above, and other motives will also exert influence. The combination of those cognitive and motivational factors is what will determine what the person will do or prefer in the situation, as the person chooses among the options and courses of action he or she sees as potential resolutions in the situation.

The final type of work on self-control or self-regulation that I would like to raise here is work showing that positive affect influences motivational processes that involve choice of behavior and expectation of outcome, and do so in some specific ways that depend on the opportunities and realities of the situation, not the person's affect alone. There are two lines of work of this kind that I will discuss, work on positive affect and intrinsic and extrinsic motivation, and work investigating the influence of positive affect on the components of expectancy motivation. Both of these lines of work show that positive affect fosters detailed, realistic consideration of the whole situation, including others' needs as well as one's own.

INTRINSIC MOTIVATION

In one series of studies, it was found that people in whom positive affect had been induced showed more intrinsic motivation than controls, but also responded well to extrinsic motivation when the work-task needed to be done (Isen & Reeve, 2005). Intrinsic motivation was measured in a free-choice situation by (1) choice of a more interesting task, over a dull task that had a very small chance of paying a small amount of money; and (2) increased amount of reported enjoyment of the enjoyable task (but not the dull task). These are standard measures used in the intrinsic motivation literature (e.g., Deci & Ryan, 1985). However, when participants were informed that there was some work that needed to be done (no money was involved this time), and again they had the choice of what activity to do during the 20-minute time period, they chose to do the work that needed to be done, but spent the rest of their time with the more enjoyable task, and thus spent more time than controls on the interesting task (even though they got their work done and did not make any more errors than the control group—both had very low error rates). They again liked the enjoyable task more than controls, but showed no difference from controls on the dull work task. Thus, they displayed self-control in the sense that that term is normally used—they did not like the work task as much as the puzzle task, but they engaged it as much as was necessary.

EXPECTANCY MOTIVATION

The other set of studies on motivation that relates to self-control that I want to mention are two showing that positive affect influences the three components of expectancy motivation (see, e.g.,

Ilgen, Nebeker, & Pritchard, 1981; Kanfer, 1990, for discussions of the theory of expectancy motivation). In a moderate range of performance (but not at extremely high or extremely low performance levels), people in positive affect saw more connection between how hard they tried and how well they would do, resulting in greater motivation that is based on their realistic expectations in the situation (see Erez & Isen, 2002 for more detail and discussion). This is not just a matter of motivation in the sense of “trying harder,” but reflects how effective the person expects to be if he or she tries moderately hard. The results indicate that people in the positive-affect condition have greater expectation that their effort will pay off (where it is likely to pay off, but not where it is not), and this is the source of trying. This is important for self-control, because it prompts people to put forth effort and stay at tasks, in the expectation that trying will lead to success and the desired outcome.

OMISSION DETECTION

Another matter of very great theoretical importance is omission detection, which of course has been investigated extensively in the consumer literature (e.g., Kim et al., 1996; Sanbonmatsu, Kardes, Houghton, Ho, & Posavac, 2003). I did not mention this topic as a focus within this chapter at the outset precisely because it *has* been investigated extensively within the field of consumer behavior, and in fact many of the most important advances in understanding its determinants and effects have been explored in those contexts. It is also investigated in the theoretical Psychology literature, most recently by Dunning and his students and colleagues (e.g., Caputo & Dunning, 2005), who have pointed out the damaging and problematic consequences of not realizing what we do not know. However, I do want to bring the topic of omission detection up in this chapter, because based on much of the discussion in this chapter, it seems possible for positive affect to play a role in enabling people to see what is missing, what they are not considering, and thus for positive affect to link these two streams of research (e.g., Mantel et al., 2006).

That is, if positive affect leads people to be more flexible thinkers, as has been widely demonstrated in the literature—to solve problems requiring a creative or innovative approach to looking at the functions or aspects of stimulus elements available for solving the problem; to think of unusual associates to stimuli; to categorize more flexibly; to understand and welcome mildly unusual brand extensions—as well as the newer effects that have been proposed to result from such flexibility and discussed in this chapter (broad focus of attention, broadened and built-up approaches, resources, and skills; improved incidental learning and ability to divide attention among tasks; and increased cognitive monitoring ability and tendency to check)—then it also seems likely that positive affect could lead people to notice missing information or material that they are not considering that they should be considering. This link has not yet been explicitly made between these two streams of research.

However, the role of affect in influencing omission detection has recently begun to be studied (e.g., Mantel et al., 2006). It is clear, from the foregoing discussions of the critical predictions for each of the phenomena described so far that follow from the findings on positive affect, that positive affect should improve omission detection. That is, the flexibility that has been demonstrated to result from positive affect should lead to noticing when one is not considering all of the important relevant aspects of a situation or problem. A recent series of studies is offering indication that, indeed, positive affect may help to reduce the problem, in judgment and decision making, of not realizing that there is important information that is missing (Mantel et al., 2006). In one study, those authors have found that people in positive affect, when given only a small number of product attributes as a product description for a product they are asked to evaluate, are more likely than controls to ask for additional information, and without the additional information, are less

extreme in their evaluations of the product. A second study, based on the Ellsberg (1961) paradox, found that where the risk in the situation was undeclared, people in the positive affect condition were less likely than controls to take the risky option. As noted earlier, we know from previous research that people in positive affect are less likely to take a risk if the risk is high and real (e.g., Isen & Patrick, 1983; Isen & Geva, 1987). But in the case under discussion, the results indicate that they are less likely to take the risky option when the risk is unspecified. Together, these results suggest that people in positive affect are more likely to notice when important information is missing from a decision situation. This line of work is just beginning, and much more needs to be done, but it is an exciting area for development, because the ability to notice missing information has so many important implications, both theoretically and in understanding the choices and behavior of consumers.

CONCLUSION

It is well-known that theoretical issues can have important practical implications, which is as it should be. Such implications have been discovered in the area of affect and cognition, where basic findings regarding affect's influence on thought processes have been explored in applied contexts such as consumer behavior, managerial decision making, and medical decision making, and found to contribute to our understanding of the processes that underlie important phenomena in applied domains. For example, the finding that positive affect leads people to consider more aspects of situations and integrate that material is relevant for many fields, from consumer decision making to managerial decision making to physician diagnostic processes. Current developments in theoretical research domains offer exciting new directions for applied work relating basic processes to consumers' behavior and decision processes, and we can look forward to continued new applications of this and other work. At the same time, the applied research has a history of contributing back to theoretical development itself, in part because the richness of the contexts in which the applied work takes place offers the opportunity to add shadings, detail, nuances, and specifics that help to expand and refine the theoretical work. We can all look forward to these developments as well.

ACKNOWLEDGMENT

Thank go to Frank Kardes for helpful comments on an earlier draft of this chapter.

NOTES

1. A few exceptions to this general statement can be found, for example, in advertising, in which we sometimes see fear appeals or annoying, repetitive ads that probably induce negative affect in consumers.
2. There is a substantial body of interesting work in consumer psychology developing on topics related to *fluency* as a meta-cognitive cue influencing affective and cognitive judgments (see, e.g., Pham, 2004; Schwarz et al., 1991). In the present context, I am considering the inverse—the influence of affect on the tendency to know what one knows (see, e.g., Nelson, 1996).
3. Of course, in extreme or emergency situations that will not be true, as one motive will take precedence; but such situations are not the focus of much of the needed research that is done on human decision making, choice, and behavior, and are not the common, everyday situations that are so in need of clarification.

The Nature and Role of Affect in Consumer Behavior

JOEL B. COHEN

University of Florida

MICHEL TUAN PHAM

Columbia University

EDUARDO B. ANDRADE

University of California, Berkeley

In the intervening years since publication of the chapter “Affect and Consumer Behavior” (Cohen & Areni, 1991) in the *Handbook of Consumer Behavior* (Kassarjian & Robertson, 1991), research in consumer behavior dealing with affect has exploded, making it one of the field’s central research topics. Within psychology more generally, Schimmack and Crites (2005) located 923 references to affect between 1960 and 1980 and 4,170 between 1980 and 2000. Since research on affect has become more specialized, this chapter will concentrate on the various ways affect influences judgment and choice rather than on broader and historical perspectives. These will include the role of affect in information retrieval, differential processing of affectively colored information (including the role of affect in strengthening mental associations and memory consolidation), how and when affect provides information that influences judgments and decisions, and the motivational role of affect in guiding behavior and signaling the need for changes in vigilance, intensity, and direction. We begin, however, with some essential definitions.

THE NATURE AND STRUCTURE OF AFFECT

On Affect: Feelings, Emotions, and Moods

What affect means

There is still some carryover from the use of the term “affect” to also refer to what is, in essence, the evaluative aspect of attitudes. This stems from the classic tri-partite depiction of attitudes: cognitive, affective, and conative (see Eagly & Chaiken, 1993) and a failure to adequately differentiate between evaluative measures (e.g., favorable/unfavorable) and antecedent or subsequent processes, which might be feeling-based. Consistent with most recent scholarly discussions, we reserve the term “affect” to describe an internal feeling state. One’s explicit or implicit “liking” for some object,

person, or position is viewed as an evaluative judgment rather than an internal feeling state. As Russell and Carroll (1999a) put it:

By *affect*, we have in mind genuine subjective feelings and moods (as when someone says, 'I'm feeling sad'), rather than thoughts about specific objects or events (as when someone calmly says, 'The crusades were a sad chapter in human history'). (pp. 3–4)

This chapter maintains the separation of affect as a feeling state that is distinct from either liking or purely descriptive cognition. So when we use the term “affect” to describe stimuli, internal and overt responses, it is only in relation to evoked feeling states. Imagine, in contrast, an advertisement whose words or images connote a happy (i.e., successful) outcome. Affective processes cannot merely be assumed. Alternative explanations (e.g., the advertised product seems likely to produce favorable outcomes) for so-called “affective” influences on subsequent evaluations and behavior must be ruled out before implicating affect. These include semantically associated changes in object meaning or construct accessibility.

This definition also raises both philosophical and empirical questions about whether such a feeling state must be consciously experienced or whether we can be unaware that we are experiencing affect. Research where subliminally presented smiling or frowning faces were used to prime affect (outside of awareness) and bring about subsequent evaluative responses (Winkielman, Zajonc, & Schwarz, 1997), is a case in point. Affective experience in the absence of an identified basis for that experience has been a staple of psychological research since Zajonc's (1980) early work on “mere exposure.” In that program of research, repeated subliminal exposure to unfamiliar stimuli having neutral valence such as Chinese ideographs has been shown to generate some degree of liking for the stimuli, possibly as a result of a primitive reward mechanism associated with increasing familiarity or a reduction in uncertainty. Another standard paradigm for investigating precognitive affective processes is to present (outside of awareness) a stimulus known to evoke either a negative or positive affective response (e.g., a sad face). Following that exposure, people are asked to indicate how they are feeling (to rule out more conscious affective responses including inferences) and to rate the emotional quality of a semantically unrelated object, such as a piece of music. Using such a procedure, for example, Strahan, Spencer, and Zanna (2002) found that affective stimuli can influence positive/negative assessments even without producing a measurable effect on people's affective experiences (i.e., reported feelings). In a particularly sophisticated study (Schmuck, 2004), subjects received masked subliminal presentations of pleasant and unpleasant pictures, followed by supraliminal presentations of an identical picture (the target) paired with a foil whose valence was either the same as the target or opposite. If the initial subliminal target exposure produced a spontaneous affective experience, participants should be better able—and they were—to discriminate the target from the foil when they had a different valence because only one object should match the originally experienced affect. Different results have frequently been observed for pictures and words when used as subliminal stimuli (Schmuck & Crites, 2005). Words have been found to elicit a skin-conductance response under conditions of very short exposure (suggesting affective experience), whereas pictures have not. However, this finding may also be due to the greater inherent polarity of the selected words relative to pictures, since the interpretation of pictures may require more cognitive resources than words having relatively fixed affective associations.

Most consumer research on affect deals with moods (e.g., Barone, Miniard, & Romeo, 2000; Cohen & Andrade, 2004; Gorn, Goldberg, & Basu, 1993; Pham, 1998), although there has been growing interest in the study of specific emotions (e.g., Lerner, Small, & Loewenstein, 2004; Raghunathan & Pham, 1999; Raghunathan, Pham, & Corfman, 2006). Moods are usually thought of

as low intensity and diffuse affective states that generally lack source identification.¹ The individual, prompted either by physiological or hormonal/chemical activity (such as changes in levels of serotonin and dopamine) or by external stimuli (music, weather, exposure to happy versus sad information), experiences a vague sense of feeling good or bad without necessarily knowing quite why. Some days or after certain experiences, we are aware of feeling good or bad, optimistic or pessimistic, up or down, relaxed or restless, alert or drowsy. Mood states also track our bodily energy levels (e.g., blood glucose levels), our daily circadian rhythm, and our general wellness or illness, thereby guiding relatively automatic self-regulatory responses as well as more conscious decisions, as we shall discuss later on. Emotions, on the other hand, are much more differentiated and hence provide more attitude- and behavior-specific information. Feeling anger, for example, will often lead to target and context-specific responses rather than more general displays of unhappiness (Bushman & Baumeister, 1998). It should be noted, however, that specific emotions can produce mood-like effects (e.g., being angry or sad can affect a pattern of behavior) often without realizing that one has transferred the emotional response (to an identified target) to unrelated behaviors. Recent studies show that the degree of transfer will be a function of two factors: (1) the salience of the source of the emotional state—transfer is more likely when the actual source of the affect is not salient; and (2) the domain similarity between the actual source of the affective state and the objectively unrelated behavior (Raghunathan, Pham, & Corfman, 2006).

Moods have been shown to be easily manipulated through exposure to affectively charged stimuli such as music, videos, and pictures, or through the recall of emotionally involving experiences (e.g., Cohen & Andrade, 2004). Note that the use of low intensity emotion manipulations, such as sadness, displeasure, or happiness, to create positive or negative mood states tends to blur the line between emotions and moods, especially when the source is made salient.

Because affect is often used as information (Schwarz, 1990; Schwarz & Clore, 1983), the misattribution of incidental affect may play a powerful role in everyday life. Even experimentally-induced proprioceptive feedback of head nodding or shaking can lead a person to conclude that message-related thoughts are positive or negative (Brinol & Petty, 2003). The duration of mood changes is typically assumed to be short, from a few minutes to a couple of hours (Isbell & Wyer, 1999), although this duration probably varies with the method of instigation (Ehrlichman & Halpern, 1988; Isen, Clark, & Schwartz, 1976).

Experimental manipulation of affective states

Multiple techniques have been used to manipulate individuals' transient affective states. In most experiments, participants are exposed to a sequence of ostensibly unrelated studies, where the first study is meant to manipulate people's feelings while the second assesses the dependent variables of interest. In the first study, participants might be exposed, for instance, to false positive or negative performance feedback (Barone, Miniard, & Romeo, 2000; Swinyard, 1993), cheerful or depressing movies (Andrade, 2005; Cohen & Andrade, 2004), pleasant or unpleasant music (Gorn, Goldberg, & Basu, 1993), or positive or negative affective self-referential statements such as the Velten procedure (Velten, 1968), unexpected gifts (Barone, Miniard, & Romeo, 2000; Isen & Simmonds, 1978). Alternatively, participants may be asked to recall and describe an affectively-charged experience in writing (Pham, 1998). Due to their transient and mild, hence, short-lived nature, experimentally induced moods may dissipate relatively fast (see Isen, Clark, & Schwartz, 1976). Therefore, regardless of the mood induction procedure, the dependent measure usually is collected not long after the manipulation. Sometimes the mood manipulation and dependent measures co-occur. Mood manipulations using background music or physical ambience, like scent, for instance, allow for a

simultaneous assessment of dependent variables (Grunberg & Straub, 1992; Schwarz, Strack, Kommer, & Wagner, 1987).

There is no single best option among all potential techniques. Different techniques raise different issues in terms of potential confounds, control for intensity levels, reliability, demand characteristics, and motivational requirements. For instance, receiving an unexpected gift, a common manipulation of positive mood (Isen, Shalcker, Clark, & Karp, 1978; Kahn & Isen, 1993), can activate norms of reciprocity independently of affective changes (e.g., “The experimenter was nice to me, I’ll be nice to him/her”). Similarly, false performance feedback can influence self-esteem or self-efficacy along with desired changes in affective states (Hill & Ward, 1989). Such unwanted effects might be confounded with the affect manipulation depending on the research question and other aspects of the procedure.

Asking participants to report an affectively charged personal experience can avoid some of the above-mentioned concerns. A major advantage of this method is that because each participant recruits his or her own personal experience, there is a lesser chance of confounding with the *content* of the affect-inducing event. Content-related confounds are much more likely with manipulations that involve exposure to a *common* affect-inducing stimulus across participants, such as watching a happy or sad movie. On the other hand, the personal experience method requires relatively high participant motivation; otherwise, the manipulation tends to be weakened. A second drawback of this method is that participants usually are explicitly directed to write about experiences that lead them to feel good or bad, which may enhance the likelihood of hypothesis guessing and demand artifacts. This concern is heightened if a salient mood manipulation check is administered before the dependent measures are collected. In addition, there may be extra variability in emotional states induced—hence higher experimental error—because participants may have different interpretations of the type of experience they are supposed to report. Some respondents may interpret “an event that made you feel bad” as one that made them feel angry, whereas others may interpret it as one that made them feel sad. It is therefore important that the instructions be very precise when using this manipulation.

Music does not require highly motivated participants, does not direct participants to specific feelings, and has been shown to produce significant effects on judgment and behavioral measures (Gorn, Goldberg, & Basu, 1993; Gorn, Pham, & Sin, 2001). However, there is significant variance in the population when it comes to music tastes, which can compromise reliability. Exposure to affectively charged videos has proven to be quite successful due to the general appeal of these stimuli (low motivation required), their easy-to-determine valence, and their higher intensity, compared to written or audio stimuli. However, as mentioned before, using a common video across participants within a given mood condition raises the possibility of confounding between affective experience and the semantic or episodic content of the video. To try to mitigate this problem, one can consider using different stimulus replicates across conditions or experiments. Another potential drawback of video-based inductions is that, compared to other procedures, exposure to videos may also facilitate hypothesis guessing and, consequently, demand artifacts. To avoid such concern, the cover story must be convincing and, also importantly, the affect manipulation check disguised. For example, Cohen and Andrade (2004) used a combined technique of video plus personal experience, in which participants were informed that the university, in order to augment its web-based teaching environment, attempted to assess the impact of audio and video stimuli transmitted through the web. Students were informed that they would watch five minutes of a video and then would perform memory and judgment recall tasks. After the video, the “memory task” instructed them to write a personal story related to the scenes watched in the clip. After the “memory task,” a “judgment task” (in fact, the manipulation check) asked participants to assess ten items related to the

video. Only three of them were affect-related. The other items were in line with the general cover story. This manipulation has shown strong and reliable effects on people's feelings and, importantly, very low incidence of hypothesis guessing (see also Andrade, 2005).

Videos have also been used to manipulate specific emotional states, such as anger (Andrade & Ariely, 2007; Phillipot, 1993) sadness and disgust (Lerner, Small, & Loewenstein, 2004), and fear (Andrade & Cohen, 2007b). Restricting the effect to one specific emotion may be challenging; some video manipulations can enhance more than one specific affective state at the same time. For instance, Gross and Levenson (1995) showed that an anger manipulation tended to increase disgust levels as well. As they pointed out, "With films, it appears that there is a natural tendency for anger to co-occur with other negative emotions" (p. 104). Still, videos and some combined techniques (video and personal story writing) are relatively successful affect manipulations (Westermann, Spies, Stahl, & Hesse, 1996).

Physiological and cognitive antecedents of emotion

The influential James-Lange theory (James, 1884) held that emotional stimuli elicited bodily responses, that is, peripheral activity such as changes in heart rate, blood pressure, and skin conductance, and that these bodily responses were translated fairly directly into conscious differences in emotional experience (e.g., fear versus anger). While there was modest success relating "energetic" physiological responses to higher arousal negative affect (compared to lower arousal states such as sadness and guilt), there was no consistent translation of bodily responses into differential positive affect. More generally, such physiological measures do not appear to reflect essential differences in the valence of emotion (Bradley, Cuthbert, & Lang, 1993; Schimmack & Crites, 2005). One response to the failure to support the James-Lange theory was to search for other, more sensitive indicants of emotional response that could then be interpreted as particular types of emotion. Facial feedback theories identified patterns that corresponded to happiness, surprise, sadness, fear, anger, and disgust (Ekman, 1973; Izard, 1977; Kleinke, Peterson, & Rutledge, 1998). However, a meta-analysis of these studies (including those where participants were induced to adopt musculature associated with smiling and frowning) indicated that these effects were too weak to perform the central function ascribed to bodily responses in the James-Lange theory (Matsumoto, 1987).

A more basic challenge to the original theory was to question the central role of bodily response to subsequent emotional experience. Schachter and Singer (1962) made significant inroads by showing (via injections of either epinephrine or a placebo) that peripheral arousal only differentiated an emotional response from merely cognitive responses. In their two-factor theory, cognitive processes played the decisive role in interpreting the arousal that was being experienced. A substantial challenge to the bodily arousal component of this theory can be seen in other research conducted at about the same time. Lazarus and Alfert (1964) asked people to watch a film depicting a tribal ritual involving what appeared to be genital mutilation. However, half of those watching were given misinformation that the experience was actually not painful and that adolescents looked forward to this initiation into manhood, and significant cognitive control over arousal was observed. Subsequent research on spinal cord injured patients best supports the view that peripheral arousal is not necessary to the experience of emotion, but can intensify it (Mezzacappa, Katkin, & Palmer, 1999). However, the importance of emotional intensification should not be minimized. Recent research on memory, for example, demonstrates the importance of such emotional experience to memory consolidation, and is, thus, consistent with evolutionary underpinnings of classical conditioning (Cahill & McGaugh, 1998). More generally, emotional response was shown to be far more under cognitive control and appraisals of experience than had been imagined.

Since then, cognitive appraisal theories have dominated research on emotion (see Scherer, Schorr, & Johnstone, 2001, for current theoretical perspectives). While emotional underpinnings may be somatic, and in that sense have significant evolutionary value in predisposing the body toward approach/appetitive or avoidance/inhibitory action, modern theories point to relatively few hardwired connections to discrete emotional states (Oatley & Johnson-Laird, 1987; Ortony, Clore, & Collins, 1988). Instead, such theories stress the involvement of cognitive appraisal (Scherer, Schorr, & Johnstone, 2001). These appraisal processes assign evaluative meaning to objects and events (i.e., desirable versus undesirable) and facilitate causal attributions to sources either in the external world, such as another person's actions or in our own behavior or thoughts. The combination of evaluative meaning, assessment of internal versus external causation and responsibility, and temporal perspective is then assumed to produce such highly differentiated emotions as happiness, pride, envy, disgust, sadness, anger, and fear (see Lazarus, 1991). While research supports the role of arousal in the experience of relatively intense emotions, cognitive processes (e.g., telling someone that an experience is/is not painful) play a major role and have been shown to alter the experience even when assessed by heart rate and skin conductance.

Building on earlier work by Leventhal (1980), Buck (1985), and Hoffman (1986), Cohen and Areni (1991) advanced a three-phase dynamic model in which activation of a mental concept (e.g., identification of a flashing red light) produces a largely unconscious and very rapid, sensory-level affective response. Some such responses may be largely innate (e.g., surprise) or at least potentiated by evolutionary processes (e.g., responses to taste; Steiner, Glaser, Hawilo, & Berridge, 2001). Others require very little learning beyond simple association to become generalized tendencies, such as preferences for smiling and familiar faces. These phase-one emotional responses interrupt other cognitive processes, orient attention, and bring resources to bear on the instigating stimulus. In phase two, the cognitive system attaches somewhat greater meaning to the stimulus by automatically extracting easily processed stimulus information and associating it with experienced pleasantness/unpleasantness and arousal. Thus, the second-phase affective response becomes more differentiated through the operation of associational, rather than reasoning processes. In phase three, affective experience results from cognitive elaboration, thereby taking into account context and previous experience. At stage two, and to a much greater degree at stage three, cognitive appraisal can enhance or suppress arousal (Lazarus & Alfert, 1964) as well as create more nuanced feeling states, such as disgust rather than sadness.

Memory for affective experiences

There is considerable evidence that the arousal intensity of an affective experience increases people's immediate and long-term memory for this experience (Bradley, Greenwald, Petry, & Lang, 1992; Kroeber-Riel, 1979; Thorson & Friestad, 1989), especially with respect to the central elements of this experience (Christianson, Loftus, Hoffman, & Loftus, 1991). This appears to be the case even when the source of arousal is unrelated to the material to be learned and comes after the learning has taken place, which suggests that the phenomenon may be due, in part, to a better consolidation of memory traces under high emotional arousal (Nielson, Yee, & Erickson, 2005). Emotional intensity is no guarantee of memory accuracy, however. Biases due to changes in cognitive appraisals of the events or revised standards of judgment (e.g., looking back, a person may have a different perspective on the emotion-eliciting event) as well as a desire to see things differently (e.g., when anticipating a recurrent experience such as childbirth) may intrude on people's memory (Levine, 1997; Levine, Prohaska, Burgess, Rice, & Lauthere, 2001). Retrospective assessments of affective experiences also seem to be more impacted by intensity at both the peak and the end of the expe-

rience, with duration playing a less significant role (Ariely & Loewenstein, 2000; Fredrickson & Kahneman, 1993; Kahneman, Fredrickson, Schreiber, & Redelmeier, 1993).

The Structure and Assessment of Affect

There are two separate research traditions among those whose work involves the assessment of affect. The first is to identify the underlying dimensions of affect by analyses of judged similarities and semantic differential ratings of mood terms, as well as facial and vocal emotional expressions. The second combines a more functional/motivational analysis with evidence from studies of neurophysiological and hormonal processes.

The first body of work supports the existence of two general dimensions: pleasantness versus unpleasantness and activation/arousal/engagement (see Remington, Fabrigar, & Visser, 2000; Russell & Carroll, 1999a; see Russell & Carroll, 1999b; Watson, Wiese, Vaidya, & Tellegen, 1999). Research in this tradition is heavily measurement-based and has been extended into several practical domains to classify affective responses to stimuli of interest, such as pictures and advertisements, as well as to provide a more general basis for delineating categories of emotional response (Watson & Tellegen, 1985).

Affect taxonomies in consumer research

Researchers with a primary interest in affective aspects of stimuli, such as advertisements and how people describe their affective responses to them, have been less interested in the underlying dimensionality of affect and often prefer to think in terms of affect taxonomies that correspond to more macro-level constellations or prototypes (Shaver, Schwartz, Kirson, & Oconnor, 1987). They rely on specially constructed inventories of mood and emotion terms, as well as scales that have been developed for other purposes (e.g., to represent appetitive and aversive motivational systems). In research on advertising, for example, Holbrook and Batra (1987) began with over 90 items that combined emotional responses and evaluative reactions to advertising content, and Edell and Burke (1987) used a 69-item inventory of feelings. In such research, investigators typically attempt to reduce the individual items to distinct clusters using techniques such as factor analysis and hierarchical cluster analysis (Shaver, Schwartz, Kirson, & Oconnor, 1987). At times, claims are made about underlying structure, but the generality of such claims is questionable because of the arbitrary selection of items and stimuli, the ambiguity of hierarchical configurations of emotion terms, as well as measurement issues to be discussed below (see also Mano, 1991; Schimmack & Crites, 2005). Nevertheless, such research may serve the investigator's needs in differentiating between types of affective responses to content and situations (e.g., store settings) of particular interest. Much of the earlier affect taxonomy research in consumer behavior, at least through 1990, was reviewed by Cohen and Areni (1991), and so it will not receive explicit attention here.

An extremely comprehensive analysis of many of the emotion measures used in consumer research was carried out by Richins (1997), who identified shortcomings in their ability to address a greater variety of consumption experiences. These included the contemplation, purchase, use, and subsequent reactions to a broad variety of products and services from the mundane to the important and sentimental (see also Derbaix & Pham, 1991). She identified a list of 175 emotion terms that had been used in consumer research and that satisfied criteria developed by Ortony, Clore, and Collins (1988) to screen out nonemotion terms focusing on bodily states such as "sleepy," subjective evaluations such as "feeling confident," behaviors and action tendencies such as "crying" and "hesitant," and cognitive states such as "interested." She supplemented this list by prompting open-ended self reports of positive and negative feelings (most commonly, the positive affective

terms “happiness,” “relief,” and “excitement,” but also “worry,” “sadness,” and “guilt”) to a variety of consumption experiences. Although the underlying dimensionality of the resulting “Consumption Emotion Set” (CES) is somewhat ambiguous (beyond the traditional positive-negative axis), the instrument appears to be quite useful for those who wish to assess consumers’ affective responses to a more comprehensive set of consumption experiences.

Underlying dimensions: The bipolarity of affect

More basic research on the structure of affect attempts to identify relationships among two primary components of affect, pleasantness, and arousal/activation. Russell (1980) originally proposed that these two dimensions be viewed as a circumplex, that is, a model in which individual mood and emotion descriptors are systematically arranged around the perimeter of a circle. Data from Russell and Barrett (1999) indicate that affective structure actually falls somewhere between a classic simple structure in which the variables cluster in dense groups around labeled axes and a true circumplex, as in Figure 11.1, in which the variables are more evenly spaced and define a complete circle.

Within this measurement tradition, there has been a debate over the bipolarity versus independence of positive and negative affect. When people experience and report high negative affect, does that mean that positive affect is low (i.e., bipolarity)? When thinking about implications of bipolarity, it is important to differentiate between “core affect” (Russell & Barrett, 1999) and evaluative outcomes of affective processes. The latter are the result of cognitive appraisals and clearly allow for mixed assessments (i.e., positive in some respects and negative in others). Core affect, on the

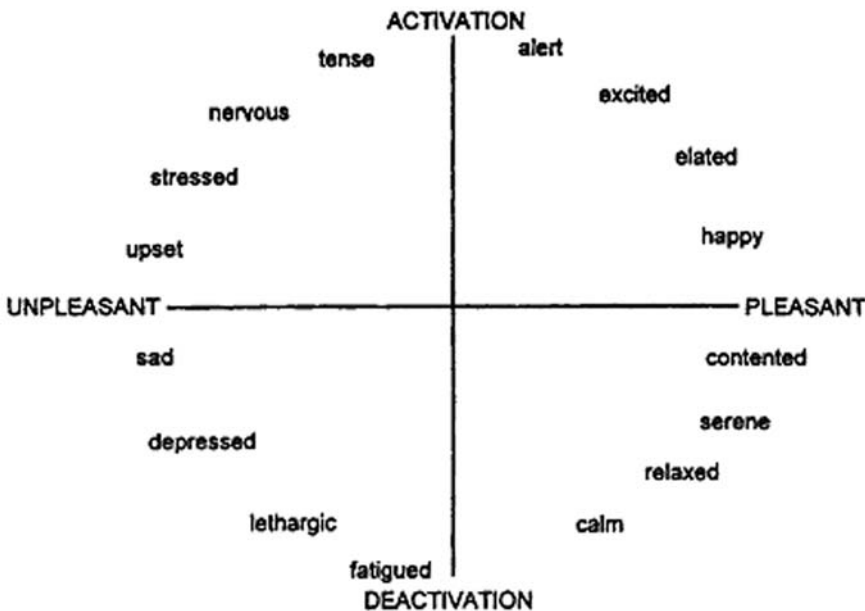

Figure 11.1 The circumplex model of affect. The circumplex model describes affect in terms of the two orthogonal dimensions of valence and activation. From “The structure of current affect: Controversies and emerging consensus,” by L. Feldman Barrett and J. A. Russell, 1999, *Current Directions in Psychological Sciences*, 8, 11. Copyright 1999 by the American Psychological Society. Reprinted with permission.

other hand, refers to how a person is feeling emotionally at a point in time. Also, when the analysis is performed at an aggregate-level across emotional experiences over time, bipolarity assumptions do not necessarily predict independence. People who are asked to report emotional states using experience sampling diaries are just as likely to have self reports indicating high average negative (positive) affect, regardless of their average levels of positive (negative) affect (Diener & Irannejad, 1986; Diener, Smith, & Fujita, 1995).

A general consensus has emerged that a bipolar structure dominates (see Russell & Carroll, 1999a), as acknowledged even by original proponents of the independence assumption (see Watson & Clark, 1997; Watson, Wiese, Vaidya, & Tellegen, 1999). While interested readers should consult the extensive literature directly, several key issues must be noted. First, tests of independence versus bipolarity require truly independent measures of positive and negative affect. Using bipolar items (e.g., -3 = sad, 0 = neutral, +3 = happy) artificially promotes bipolarity. On the other hand, using unipolar items often leaves the lower endpoint of the scale ambiguous. For example, if respondents are asked to rate their happiness on a 1–5 scale going from “not at all” to “extremely,” does a “1” mean a mere absence of happiness or an opposite state such as sadness? In addition, where does neutrality lie in such a scale? Such measurement issues can have major influences on the factor structure of the resulting scale.

Even assuming independent measurement of positive and negative affect, the bipolarity of specified circumplex axes (corresponding to particular affective states shown in Figure 11.1 and measured by various scales) has proven to be far more problematic. A primary reason is the confounding caused by variations in arousal/engagement that prevent the semantic opposites in Figure 11.1 from lying along a 180° angle. Across a number of such studies, positive and negative affect have been found to be moderately negatively correlated (typically around $r = -.44$) rather than nearly perfectly negatively correlated, implying bipolarity, or nearly perfectly uncorrelated, implying independence (Diener, Smith, & Fujita, 1995; Watson, Clark, & Tellegen, 1988; Watson, Wiese, Vaidya, & Tellegen, 1999). However, the correlation increases dramatically when people report affect in the presence of strong, intense emotion (Diener & Irannejad, 1986), demonstrating the bipolarity of strong emotional states. On the other hand, feelings originally characterized as low positive affect (hence low in activation/arousal) and that correspond to quietude and calmness are not far removed from low negative affect states (e.g., sluggish) characteristic of mild depression. Consider a person who views himself as experiencing a lack (or loss) of pleasure or lack of response to pleasurable stimuli. At low levels, then, self reports of positive and negative affect can be positively correlated (Watson, Wiese, Vaidya, & Tellegen, 1999), suggesting independence.

Underlying neurophysiological processes clearly register and potentiate positive and negative affect simultaneously. Though conflict and/or ambivalence would seem to be logical consequences of events and stimuli that simultaneously prompt fear and excitement, making effective reactions difficult, emotional paralysis is not the norm. A great deal of current research beyond the scope of this chapter is providing substantial insight about how these underlying neurophysiological processes translate into more molar responses. We will discuss some relevant work on “mixed emotions” a bit later.

The PANAS scales: Combining valence and activation

Consumer researchers rely heavily on the positive and negative affect scales of the PANAS (Watson, Clark, & Tellegen, 1988). The positive cluster consists of active, alert, attentive, determined, enthusiastic, excited, inspired, interested, proud, and strong. The negative cluster consists of afraid, ashamed, distressed, guilty, hostile, irritable, jittery, nervous, scared, and upset. While this

instrument has proven to be useful in many studies, there are two significant issues that consumer researchers should consider. First, the two scales do not cover the full range of positive and negative affect. Pleasant states of low to moderate activation (e.g., happy, positive, satisfied, serene, pleased) are missing from the positive affect (PA) scale where high activation states (e.g., active, alert, attentive, excited) predominate. Unpleasant states of low to moderate activation (e.g., unhappy, negative, depressed, sad) are also missing from the negative affect (NA) scale where high activation states (distressed, jittery, upset) predominate. This is not an oversight, though perhaps an inartful choice of labels. Watson and colleagues were clear at the outset that they wished to capture a combination of positive affect *and* activation (and the same enhanced activation on the negative side). In effect, Watson and Tellegen (1985) rotated the axes 45° to attempt to focus on two orthogonal dimensions that they now term positive activation and negative activation (Watson, Wiese, Vaidya, & Tellegen, 1999).

The functional significance of these two dimensions was recognized by Fowles (1994). PA corresponds to affect that energizes and facilitates approach behavior and reward seeking; whereas NA corresponds to affect that inhibits similar behavior and leads instead to avoidance—a “stop, look and listen” response to the environment. Considerable research in neurophysiology is being directed to understanding the processes responsible for these appetitive and aversive effects, but that is beyond the scope of this chapter (for a review, see Lang, 1995).

Most recently, then, affect researchers have been redefining the PANAS instrument to more appropriately recognize its measurement of positive activation and negative activation (J. T. Larsen, McGraw, & Cacioppo, 2001; Schimmack & Crites, 2005). The second and related problem with the PANAS instrument is that it violates the semantic-opposites requirement listed earlier for a test of bipolarity. Only positive affective states of high activation are semantically opposite (180° away) of negative affective states of low activation. Russell and Carroll (1999a) note that the negative set includes none of the semantic opposites of the positive set because the opposite of positive activation is not negative activation, but a state combining negative affect and low arousal. Accordingly, PANAS does not have psychometric properties that allow it to be used to investigate questions involving the independence of positive and negative affect.

In a reanalysis of available data, Russell and Carroll (1999a) identified three clusters of positive items that could alternatively be viewed as varying continuously in arousal. The first cluster involves positive affective states of high activation such as being enthused, ebullient, excited, and energetic. A second cluster involves positive affective states of moderate activation such as being happy, gratified, pleased and content. A third cluster involves positive affective states of low activation such as being calm, serene, tranquil and relaxed. A parallel clustering was uncovered on the negative affect side: (1) negative affective states of high activation such as being tense, upset, jittery, and nervous; (2) negative affective states of moderate activation such as being unhappy, miserable, discontent and troubled; and (3) negative affective states of low activation such as being depressed, bored, lethargic, and glum.

Mixed emotions

A person can feel sad and guilty *or* happy and proud at the same time. But is it possible to feel guilty and proud (or any other combination of oppositely valenced emotions) at the same time? Imagine, for example, being very successful in a negotiation in a third-world country that deprived the seller of money that had significantly greater value to her than to you. You might feel pride at your skill (particularly if others in your group did less well in similar negotiations), but you also may experience guilt. Do we simply shift back and forth in such emotional quandaries (alternating between

positive and negative feelings), or can we actually be happy and sad at the same time? Note that this is a different issue from an evaluation of one's behavior (which might be tempered because of oppositely-valenced emotions) or how a person would translate mixed emotions in responding to a sad-happy scale, since a person would need to resolve that conflict in order to make such judgments. Russell and Carroll (1999a) argue that the bipolarity of emotional experience implies that when you are happy, you are not sad, just as when you are hot, you are not cold. Strictly speaking, that claim is very strong since being at one point on the abscissa of an affect distribution precludes being at any other point. As Larsen et al. (2001) point out, bipolarity implies a linear relationship, and thus a correlation close to -1 . Mutual exclusivity of positive and negative affect, on the other hand, would produce intermediate degrees of independence. But does any level of correlation between measures of positive and negative affect imply that any (even low) levels of happiness preclude *experiencing* sadness? Watson and Tellegen (1999) maintained that sadness decreases as happiness increases. In that sense, happiness and sadness regularly co-occur and are only mutually exclusive when people are maximally happy or maximally sad.

Williams and Aaker (2002) employed either happy, sad, or mixed emotional appeals by combining the same picture with different characterizations of it. They found that the acceptance of the duality of emotions (via mixed emotional appeals) was greater among Asian American than Anglo Americans (who actually reported discomfort), although both groups reported experiencing a combination of happiness and sadness when given the mixed emotional appeal. Such self reports are ambiguous since it is difficult to know whether people assume they should be experiencing mixed emotions when confronted with a stimulus presenting a happy *and* sad event or could be translating their "somewhat sad" (or somewhat happy) feelings on to scales that allow them to report mixed emotions.

A well-known demonstration of mixed emotions was carried out by Larsen et al. (2001). They exposed people to a mixture of happy and sad events in the movie *Life is Beautiful* in which a father seeks to keep his child's spirits up while they are in a concentration camp. Viewers reported mixed feelings of happiness and sadness. Since people may well have alternated back and forth, in a subsequent study, Larsen et al. (2004) created a gambling context which led to disappointing wins (because people expected more favorable outcomes) and relieving losses (because people expected even worse outcomes). A button-pressing task suggested that people, in fact, experienced mixed emotions simultaneously. Note, however, that these are unlikely to be extremely positive *and* extremely negative feelings—a combination that seems difficult to imagine. So, another possibility is that people subjectively interpreted these more moderate feelings as though they were part positive and part negative in light of the information they were given. Such findings raise important questions about the nature of affective experience.

Evidence supporting mixed emotions has also shed new light into the potential processes underlying the consumption of products and services that—at least from an outside observer's point of view—are expected to produce negative feelings (e.g., watch horror movies, practice dangerous sports, etc). Andrade and Cohen (2007b) point out that previous theories tended to rely on the assumption that positive and negative feelings cannot be experienced at the same time. As a result, people who deliberately exposed themselves to apparent sources of negative feelings either do not experience much negative affect (Fenz & Epstein, 1967; Zuckerman, 1996) or focus on its relieving consequences—after removal of the aversive stimuli (Solomon & Corbit, 1974; Zillmann, 1980). Andrade and Cohen showed the importance of relaxing the single affective valence assumption in order to provide a more complete understanding of the phenomenon. In a series of four studies, it was shown that after exposing participants to horrifying scenes of a film clip (scenes from *The Exorcist*), fear approach (horror movie watchers) and fear avoidance (non-horror movie

watchers) consumers displayed strikingly similar levels and patterns of negative affect. However, fear approach consumers also showed increased levels of positive affect, whereas fear avoidance consumers showed no signs of positive experiences. Also importantly, the authors demonstrated that mixed feelings are more likely when individuals are able to place themselves within a protective (detachment) frame: “An ideal detachment frame gives people the ability to increase psychological distance from the main actors of the movie, while still absorbing the impact of the scenes” (p. 32). When presented with the actors’ biography prior to the movie, and the actors’ “regular” pictures next to the video during the scenes, which was supposed to remind the audience that these were simply actors playing a role, fear-avoidance and fear-approach participants reacted similarly, both displaying increased levels of positive or negative affective states during the movie. People tend to deliberately choose to expose themselves to sources of negative affect when a psychological protective frame is present, as it allows for the co-activation of positive and negative affect. A similar rationale has been adopted to show the presence of mixed feelings of disgust and amusement as a result of video exposure (Hemenover & Schimmack, 2004).

THE ROLE OF AFFECT IN CONSUMER JUDGMENT AND DECISION MAKING

It is useful to distinguish three types of affect in consumer judgment and decision making. *Integral affect* refers to affective responses that are genuinely experienced and directly linked to the object of judgment or decision.² Integral affective responses include momentary feelings experienced through direct exposure to the object itself (such as the pleasant feeling of tasting a fine wine) and those experienced in response to some representation of the object—a representation that may be externally provided (e.g., a TV commercial for a product) or internally generated (e.g., thinking about a product). These affective responses are integral to the extent that they are elicited by *features* of the object, whether these features are real, perceived, or only imagined.

Incidental affect refers to affective experiences whose source is clearly unconnected to the object to be evaluated. Most of the literature on mood effects on consumer behavior (e.g., Gardner, 1985; e.g., Kahn & Isen, 1993; Lee & Sternthal, 1999) deals with incidental affect in that the source of the mood is typically unrelated to the judgment or decision being made. In addition to a person’s current mood, incidental affect may also come from a person’s emotional dispositions (such as chronic anxiety or depression) and temperament (such as general optimism or pessimism), or from any contextual stimuli associated with integral affect (such as background music, pleasant scent, etc.).

Task-related affect lies somewhere between integral and incidental affect. It refers to affective responses that are elicited by the task or process of making judgments and decisions, as opposed to direct, integral responses to features of the target objects or purely incidental feelings. For example, the emotional stress of having to choose between two very attractive offers would be considered task-induced in that it is the *process* of having to choose between these two offers that is stressful, not the offers themselves. Indeed, decisions may trigger unpleasant task-related affect even when the options are associated with pleasant integral affect, for example, a choice between two vacation destinations. In the above example, the emotional stress experienced would not be incidental either because, by definition, it would not have arisen had a judgment or decision not been required. Each type of affect will be discussed separately in relation to consumer judgment and decision making.

Integral Affect in Judgment and Decision Making

The influence of integral affect on target evaluation

Numerous studies across various disciplines show that integral affective responses to a target object—whether the object is a product, a person, or a company—are often incorporated into a

summary evaluation of the object. In general, though not always, objects that elicit pleasant feelings, such as a beautiful symphony, a sweet dessert, or an attractive singer, are evaluated more favorably, and objects that elicit unpleasant feelings, such as a noisy apartment, a sour tasting dish or a rude salesperson, are evaluated less favorably. The relation between integral affective responses and object evaluation is so strong that, for a long time, affect and evaluation (or attitude) were considered to be synonymous (e.g., Fishbein & Azjen, 1975). Nevertheless, despite the generally strong positive correlation between measures of integral affective responses and measures of overall evaluation, there is growing consensus that the two constructs are theoretically and empirically distinct, with integral affective responses generally conceived as one of several potential antecedents or determinants of overall evaluation or attitude (see Breckler & Wiggins, 1989; Crites, Fabrigar, & Petty, 1994; Pham, Cohen, Pracejus, & Hughes, 2001; Wyer, Clore, & Isbell, 1999; Zanna & Rempel, 1988).

In an early demonstration of the influence of integral affective responses on summary evaluations, Abelson, Kinder, Peters, and Fiske (1982) documented in two large surveys that people's emotional responses to prominent politicians (notably, Jimmy Carter, Gerald Ford, and Ronald Reagan) were highly predictive of their overall attitudes and preferences toward these politicians. Importantly, people's emotional responses predicted their attitudes *over and above* their own party affiliation and their assessments of the politicians' traits and behaviors. A major theme of research in social psychology and consumer research during the 1980s and 1990s was that integral affective responses to various target objects may predict judgment, choice, and behavior toward these objects over and above assessments based on more descriptive or "cognitive" bases of judgments such as beliefs, stereotypes, base-rates, prior attitudes, etc. In marketing and consumer research, this theme was pursued most extensively in the advertising domain. A large number of studies have indicated that affective responses to advertisements have direct effects on consumers' attitudes toward the ad (A_{ad}) and at least indirect effects on consumers' attitudes toward the brand (A_b) through the effects on A_{ad} (cf. Aaker, Stayman, & Hagerty, 1986; Batra & Ray, 1986; Brown, Homer, & Inman, 1998; Brown & Stayman, 1992; Edell & Burke, 1987; Holbrook & Batra, 1987). Some studies indicate that ad-induced affective responses may also influence A_b directly, independently of A_{ad} . (e.g., Burke & Edell, 1989; C. M. Derbaix, 1995; Morris, Woo, Geason, & Kim, 2002; Stayman & Aaker, 1988) However, the findings probably deserve further analysis because, at the time, less attention was paid to separating actual affective responses to the ad from sheer liking of the ad. In addition, the mechanisms explaining how affect was transferred from the ad to the brand were not closely examined.

Conceptually related results have been obtained across a variety of other domains of judgment, choice, and behavior. For instance, Bodur, Brinberg, and Coupey (2000) indicated that affect toward various AIDS prevention behaviors such as abstinence or condom usage predicted attitudes and intentions toward these behaviors over and above personal beliefs about these behaviors. Similarly, Allen, Machleit, and Kleine (1992) reported that emotional responses to past blood donations predicted future donation behavior over and above expressed attitudes toward donation. Likewise, Oliver (1993) indicated that affective responses to products such as cars and a college class predicted overall satisfaction with these products over and above one's satisfaction with the products' specific attributes. In the investment domain, MacGregor, Slovic, Dreman, and Berry (2000) found that investment banking students' feelings toward various industry sectors (electronics, managed healthcare, etc.) were strongly predictive of their intentions to invest in these sectors, independent of the sectors' financial fundamentals. In summary, the literature indicates that integral affective responses to a variety of target objects influence consumers' overall evaluations of and behaviors toward these objects beyond more descriptive bases of object evaluation such as beliefs, stereotypes, prior attitude, etc. However, as noted above, some caution may be called for because some of

the studies in this line of research may not adequately distinguish actual feeling states from overall liking responses.

Underlying processes

Three mechanisms may explain why integral feelings have a direct influence on overall evaluation and behavior independent of one's descriptive knowledge about the target. The first two mechanisms both imply a noninferential, "automatic" influence of integral feelings on target evaluation. The first possibility is that integral feelings enter evaluations directly through simple evaluative conditioning. Evaluative conditioning refers to the transfer of evaluative meaning across stimuli that are presented simultaneously (see Staats & Staats, 1957); it differs from classical (Pavlovian) conditioning in that one stimulus does not serve as a signal of another (see De Houwer, Thomas, & Baeyens, 2001). A close proximity between a target and an integral feeling experience may result in the evaluative meaning of the feelings (mostly their valence) being carried over to the target—a mechanism sometimes called "affect transfer" in consumer research and marketing (e.g., Mackenzie, Lutz, & Belch, 1986). A second possibility builds on the idea that affective experiences are associated with particular action tendencies such as approach, avoidance, withdrawal, or confrontation (see Frijda, Kuipers, & Terschure, 1989). These action tendencies may not only carry over to actual behavior, but also be translated spontaneously into proxies of behavior such as evaluations and intentions. This mechanism would be consistent with the emerging view of affect as an embodied mode of evaluation (e.g., Clore & Schnall, 2005; Damasio, 1994; Forster, 2004; Zajonc & Markus, 1982).

A third mechanism is based on the hypothesis that integral affective responses are often viewed as sources of information during object evaluation (Schwarz, 1990; Schwarz & Clore, 1996). To evaluate a target, people may consciously inspect their feelings to see "how they feel" about it. Pleasant feelings would be interpreted as evidence of liking, satisfaction, well-being, and so on; unpleasant feelings would be interpreted as evidence of disliking, dissatisfaction, misery, and so on. This process is known as the "how-do-I-feel-about-it?" heuristic (Schwarz & Clore, 1988). Numerous studies have documented the existence and operation of this heuristic both in psychology (e.g., Schwarz & Clore, 1983; see Schwarz & Clore 1996, for a review) and in consumer research (e.g., Gorn, Goldberg, & Basu, 1993; Pham, 1998; Pham, Cohen, Pracejus, & Hughes, 2001). Although the heuristic was originally proposed as an explanation of incidental mood effects on judgment (Schwarz & Clore, 1983, 1988; see the discussion of incidental affect below), there is growing evidence that the heuristic is used with integral feelings as well (Pham et al., 2001). In fact, the primary application of this heuristic—its *raison d'être*—is in relation to integral affective feelings (see Pham, 2004, for a discussion). Some research indicates that the heuristic is also used *anticipatorily* in consumer decision making. Sometimes consumers appear to construct "mental pictures" of the alternatives and assess how they feel as they hold these pictures in their minds (Pham, 1998).³ (See also Gilbert, Gill, & Wilson, 2002, for conceptually related results). These pictures appear to be concrete, which explains why the reliance on momentary feelings in decision making has been found to be more pronounced among people with high imagery ability (Pham, 1998). Unlike the first two mechanisms, the "how-do-I-feel-about-it?" heuristic is assumed to be inferential, as opposed to purely associationistic or mechanistic. That is, people are assumed to *reflect* on what their integral feelings mean for the judgment to be made; they do not rely on these feelings automatically (see Avnet & Pham, 2004, for evidence consistent with this interpretation).

The three mechanisms described above all predict a direct effect of integral affective responses on evaluations. A fourth mechanism posits an *indirect* effect. It has been suggested that integral

affective responses enter evaluations only indirectly by changing the person's perceptions or beliefs about the target (e.g., Fishbein & Middlestadt, 1995). For instance, feelings of frustration toward a service provider might reinforce perceptions that "they are not reliable" or trigger beliefs that "they don't care about the customer." It is these perceptions and beliefs—not the feelings that triggered them—that are then summarized and integrated into the overall evaluation. Consistent with this mechanism, some studies indicate that affective responses to advertisements may also influence brand attitudes by changing brand beliefs (see Brown & Stayman, 1992; Mackenzie, Lutz, & Belch, 1986). This mechanism is also consistent with a major explanation of incidental mood-congruency effects on evaluations (discussed further below). According to this explanation, evaluations tend to be assimilated toward incidental mood states because these states cue mood-consistent materials in memory, which then color perceptions of the target (Isen, Shalcker, Clark, & Karp, 1978).

Properties of evaluations and decisions based on integral affect

It is widely accepted that, in general, judgments and decisions based on integral feelings are *reached more rapidly* than are comparable judgments and decisions based on descriptive inputs. Although this property was originally assumed mostly on theoretical grounds (e.g., Epstein, 1990; Zajonc, 1980), it has since been documented empirically both with stimulus-based evaluations (Pham, Cohen, Pracejus, & Hughes, 2001) and with memory-based evaluations (Verplanken, Hofstee, & Janssen, 1998). This property should logically extend to decisions and choices as well, although this prediction remains to be tested. Three factors account for the generally greater speed of judgments and decisions based on integral affect. First, integral affect often arises very rapidly (e.g., LeDoux, 1996; Zajonc, 1980). Second, integral affective responses often enter evaluations through simple associations. Finally, even if integral affective responses have to be interpreted, as they do in the "how-do-I-feel-about-it?" heuristic, their interpretation is generally very clear (Strack, 1992).

It is also widely accepted that judgments and decisions based on integral affect generally *require less processing resources* (e.g., Epstein, 1990). As a result, any constraint on processing resources (time pressure, distraction, cognitive load, etc.) tends to increase the reliance on integral affective responses both in evaluative judgments (Pham et al., 2001) and in choices (Nowlis & Shiv, 2005; Shiv & Fedorikhin, 1999). For example, when given a choice between a tempting piece of chocolate cake (an affectively attractive option) and a healthier fruit salad (a "cognitively" attractive option), consumers whose cognitive resources were not constrained tended to choose the healthier fruit salad. However, when cognitive resources were constrained, consumers tended to choose the more tempting cake, presumably because affective drivers of preference still operated while the more cognitive drivers could not (Shiv & Fedorikhin, 1999). Similarly, Nowlis, and Shiv (2005) found that distracting consumers while they are sampling a pleasant-tasting but relatively unknown brand of chocolate increases the likelihood that they will subsequently choose the sampled brand over a better-known brand of chocolate. Again, this is presumably because distraction increases the relative weight attached to the pleasant integral feelings associated with the sampling experience.

Evaluations and decisions based on integral affect also tend to be *myopic*. Immediate affective rewards and punishments tend to be weighted too heavily, whereas delayed consequences are not weighted sufficiently (see Loewenstein, 1996). This property is very salient in impulse control situations where people have to trade off the immediate hedonic consequences of an option (such as the pleasure of eating junk food or the pain of visiting the dentist) against its long-term consequences (high cholesterol and obesity; healthy teeth and gums). According to Loewenstein (1996), the myopia of affect-based judgments and decisions is caused by the differential accessibility of current and delayed affective states. Whereas the experience of immediate integral affect has strong drive

properties (e.g., the cathartic anger release of yelling at an uncooperative salesclerk), it is more difficult to anticipate and vividly picture future affective states (e.g., the embarrassment of being escorted out of the store). As a result, a reliance on affect tends to yield preferences for options that are more rewarding (or less painful) in the short term even if these options are less desirable in the long run. Consistent with this proposition, recent brain imaging studies indicate that preferences for immediate rewards are associated with greater activation in parts of the limbic system that are associated with affect (McClure, Laibson, Loewenstein, & Cohen, 2004). Affective responses, it seems, are part of a decision-making system of the present (Pham, 2004).

A lesser-known property of evaluations based on integral affect is that they *can exhibit relatively high consensus*. Contrary to popular beliefs that affect is highly subjective, a growing body of evidence suggests that affective judgments are, in fact, quite consensual, sometimes even more so than cognitive judgments. For instance, judgments of physical attractiveness, long thought to be purely subjective (“beauty is in the eye of the beholder”) have recently been shown to be largely universal (Etcoff, 1999). Similarly, emotional responses to music have been shown to be largely shared (Peretz, Gagnon, & Bouchard, 1998). It has also been observed that, although juries may disagree widely on the amount of punitive damages they are willing to award in legal cases, they tend to agree strongly on how outraged they feel in response to each case (Kahneman, Schkade, & Sunstein, 1998). In fact, for a variety of everyday stimuli, people seem to agree more on how they feel toward the stimuli than on how they would cognitively assess these stimuli (Pham, Cohen, Pracejus, & Hughes, 2001). According to Pham et al. (2001), affect-based judgments will be most consensual when the integral affective responses are triggered through hardwired programs involved in bioregulation (such as the pleasure experience of eating ice cream) or through emotional schemata acquired through conditioning and socialization (e.g., the outrage elicited by an unprovoked insult). Affect-based judgments will be less consensual when based on integral affective responses arising through controlled appraisal processes such as the guilt experienced when attributing one’s failure to a lack of effort.

Evaluations and decisions based on integral affect additionally tend to be *sensitive to the presence or absence of affect-producing stimuli but relatively insensitive to further variations in the magnitude of these stimuli*. This property was recently demonstrated in an interesting series of studies by Hsee and Rottenstreich (2004). In one study, respondents were asked to assess how much they would pay for a used collection of either 5 or 10 Madonna CDs. One group of respondents was primed to make their assessments based on how they felt toward the target (Madonna and her music); the others were primed to make their assessment in a calculating fashion. Consistent with the researchers’ predictions, respondents’ willingness to pay for the CD collection was much more sensitive to the size of the collection among respondents who had had been primed to rely on calculation than among respondents who had been primed to rely on their feelings. In another study, respondents were asked to assess how much they would be willing to donate for a rescue effort that would save either one or four pandas’ lives. For one group of respondents the number of pandas saved was simply represented by one or four dots. For the other group, the number of pandas saved was represented by one or four cute pictures of pandas, which was expected to trigger a more affective mode of evaluation. Again, as predicted, respondents’ donations were much more sensitive to the number of pandas saved in the affect-poor (dot) condition than in the affect-rich (picture) condition. Hsee and Rottenstreich (2004) explain this phenomenon as follows. Affect-based evaluations are often based on concrete mental images of the target (see Pham, 1998). Because these images are discrete, usually consisting of prototypical representations of the target (a lovely panda, a popular Madonna song), continuous quantitative information tends to be lost (Kahneman, Ritov, & Schkade, 1999).

Similarly, evaluations and decisions based on integral affect are *relatively insensitive to probabilities*, except for the presence or absence of uncertainty (Loewenstein, Weber, Hsee, & Welch,

2001; Rottenstreich & Hsee, 2001). In a telling demonstration of this phenomenon, Rottenstreich & Hsee (2001) asked respondents how much they would be willing to pay to avoid two types of negative outcomes, either losing \$20 or receiving a painful but harmless electric shock, with an either 1% or 99% probability of occurrence. Consistent with standard economic theory, respondents were willing to pay much more to avoid a 99% probability of losing \$20 (Mean = \$18) than to avoid a 1% probability of losing \$20 (Mean = \$1). However, when the decision was about receiving an electric shock, a prospect rich in negative affect, respondents were not willing to pay much more to avoid a 99% probability of shock (Mean = \$10) than to avoid a 1% probability of shock (Mean = \$7). According to Loewenstein et al. (2001), this phenomenon again arises because affective decisions and evaluations often involve anticipatory affective responses to discrete images of the options that do not incorporate probabilities. However, affect-based decisions and evaluations are sensitive to deviations from absolute certainty (i.e., from impossibility to small probability and vice versa). For example, many consumers grossly overpay to turn zero probabilities of winning in big lotteries (a prospect rich in affect) into probabilities that are infinitesimal. Similarly, most consumers would be willing to pay large insurance or security premiums to convert minute probabilities of catastrophic events (prospects rich in affect) into zero probabilities. Loewenstein and colleagues (2001) argue that anticipatory affective responses such as dread (of negative outcomes) or hope (of positive outcomes) are sensitive to *possibility* (i.e., deviations from certainty) rather than actual probability (see also Slovic, Finucane, Peters, & MacGregor, 2002).

Finally, evaluations and decisions based on integral affect tend to have a *high degree of internal coherence* (Pham, 2004). This is because integral affective responses to a target, which are often immediate and highly accessible, often trigger a confirmatory search for information that supports or helps explain these initial feelings (Pham, Cohen, Pracejus, & Hughes, 2001; Yeung & Wyer, 2004). This confirmatory search results in a strong correlation between the immediate affective response elicited by a target and the spontaneous thoughts that people associate with the target.⁴ This strong correlation in turn results in more polarized evaluations (Adaval, 2003). Consistent with this proposition, Pham et al. (2001) found, for instance, that affective feelings toward a variety of stimuli (magazine pictures, TV commercials, etc.) are almost perfect predictors of the thoughts generated spontaneously by the stimuli. Similarly, Yeung and Wyer, (2004) found that that consumers' initial affective responses to a product's appearance make them more likely to attend and weigh product attribute information that is evaluatively consistent with the valence of the initial affective responses. A review of neurophysiological evidence led Damasio (1994) to a similar proposition: "Somatic states, negative or positive, caused by the appearance of a given representation, operate not only as a marker for the value of what is represented, but also as a booster for continued working memory and attention" (p. 198). That immediate integral affect directs subsequent thoughts may partly explain why personal impressions based on very limited samples of expressive behavior (watching a 30-second video clip of an instructor teaching) are surprisingly predictive of long-term evaluations (the instructor's end-of-semester student evaluations) (see Ambady & Rosenthal, 1992). Pham (2004) speculates that the internal coherence of affect-based judgments and decisions may have had the evolutionary purpose of promoting faster and more efficient behavioral responses to the environment by increasing the intrapsychic consistency of the signals that the person receives.

Determinants of reliance on integral affect

A number of factors have been found to increase people's reliance on integral affective responses in judgment and decision making. Although some of these factors were actually identified in studies of incidental affect, they are discussed here to the extent that they apply to integral affect as well.

Because integral affective responses are easy to access, monitor, and interpret (e.g., Pham, Cohen, Pracejus, & Hughes, 2001; Wyer, Clore, & Isbell, 1999), consumers tend to rely on integral affect more when (a) their motivation to process information is low (e.g., Miniard, Bhatla, Lord, Dickson, & Unnava, 1991; Petty, Schumann, Richman, & Strathman, 1993), (b) they are distracted, cognitively constrained, or under time pressure (e.g., Albarracin & Wyer, 2001; Pham, Cohen, Pracejus, & Hughes, 2001; Shiv & Fedorikhin, 1999), (c) other bases of evaluation are ambiguous (e.g., Gorn, Pham, & Sin, 2001; e.g., Isen & Shalcker, 1982; Miniard, Bhatla, & Sirdeshmukh, 1992), or (d) they lack expertise in the target domain (Ottati & Isbell, 1996; Srull, 1987). These types of results have led some authors to theorize that the reliance on feelings in judgment and decision making is primarily a low-involvement, simplifying strategy (e.g., Clore, Schwarz, & Conway, 1994; Forgas, 1995; Petty, Schumann, Richman, & Strathman, 1993). However, the reliance on feelings is not always a low-involvement heuristic. Certain high-involvement decisions, such as who to marry or which house to buy, often seem based on affect (e.g., P. R. Darke, Chattopadhyay, & Ashworth, 2006). Sometimes, integral affective responses are considered to be very relevant for the judgment or decision to be made, even if the judgment or decision is highly involving (Pham, 1998).

Several factors have been found to influence the perceived relevance of affective responses in judgments and decisions. Affective responses to the target are perceived to be more relevant (hence, are relied upon more) under the following conditions: (a) when the consumer has experiential motives (e.g., evaluating a book as a potential beach read), as opposed to instrumental motives (e.g., evaluating a tax manual as potential help for a tax return) (Pham, 1998); (b) when the judgment or decision is inherently affective, e.g., evaluating one's satisfaction (Clore, Schwarz, & Conway, 1994; Wyer, Clore, & Isbell, 1999); (c) when the consumer makes the decision for himself or herself as opposed to someone else (Raghunathan & Pham, 1999); (d) when the consumer is promotion-focused (an inclination to use approach strategies in goal pursuit) as opposed to prevention-focused (an inclination to use avoidance strategies in goal pursuit) (Pham & Avnet, 2004); and (e) when the consumer generally trusts his or her feelings (Avnet & Pham, 2007). Overall, it appears that consumers are much more flexible in their reliance on feelings than previously thought (Pham, 2004).

Emerging research on anticipatory and anticipated integral affect

As demonstrated by Pham's (1998) research on the use of the "how-do-I-feel-about-it?" heuristics in consumer decision making, consumers often make decisions based on feelings that they experience *anticipatorily* while holding a mental representation of the target in their minds (see also Gilbert, Gill, & Wilson, 2002 for conceptually related results). These anticipatory feelings function as valuation proxies for the anticipated consequences of alternative courses of actions (Pham, 2004).

Although the two notions are often confused, the notion of *anticipatory* feelings should be differentiated from the notion of *anticipated* or *expected* affect. Anticipatory feelings refer to actual feeling experiences that arise during the decision process in the course of evaluating a target object (Bechara, Damasio, Tranel, & Damasio, 1997; Pham, 1998). Although anticipatory feelings may be subtle, they are genuine feelings with a distinct emotional quality (see Pham, 1998, Experiment 3). In contrast, anticipated or expected affect refers to *predictions* about potential affective consequences of the decision (see Loewenstein & Lerner, 2003). For example, in order to make a choice between two houses, a consumer may try to predict how happy she and her family would be in each house. This type of affect, sometimes called "predicted utility" by decision theorists (Kahneman & Snell, 1990), is central to the standard economic theory of choice, where people are posited to make choices based on the predicted hedonic consequences of the various options. These predictions appear to be strong determinants of risky choice in gambling tasks (Mellers, Schwartz,

Ho, & Ritov, 1997; Mellers, Schwartz, & Ritov, 1999). As shall be discussed later in the section on affect and motivation, expected affect also plays an important role in affect regulation where options and behaviors are chosen specifically in terms of their affect-changing or affect-maintaining consequences. However, these predictions are affective *beliefs* (i.e., cognitions), not genuine visceral feelings. Although anticipatory feelings and affective beliefs (expected affect) will naturally be correlated when the former informs the latter, there can be substantial dissociation between the two (Pham & Raghunathan, 2007; Robinson & Clore, 2002). For example, whereas genuine feelings of anxiety tend to push decision makers toward low-risk/low-reward options and genuine feelings of sadness tend to push decision makers toward high-risk/high-reward options, affective beliefs about anxiety or sadness do not have the same influences (Pham & Raghunathan, 2007). As Pham (2004) recently pointed out, the distinction between genuine anticipatory feelings and mere affective beliefs has important methodological implications. Certain methodologies such as survey questionnaires about future behavior (commonly used in attitude research) and hypothetical scenarios (commonly used in decision research) may tap into people's affective beliefs (and the intuitive theories that guide these beliefs) rather than genuine integral feelings.

An important type of anticipatory feeling is the fear response. Although such responses were examined many years ago in connection with fear appeals in persuasion (Dollard & Miller, 1950; see Eagly & Chaiken, 1993), they remain important in understanding the reluctance of people to depart from the status quo and to take action when pathways to successful outcomes are uncertain and risky. Leventhal (1970) argued that threat-related cues instigated both a problem-solving process ("danger control") and a process that focused on threat avoidance ("fear control"). To the extent the latter dominates, people may minimize or rationalize the threat and fail to take effective action. This parallel-response model influenced the development of protection motivation theory (Rogers, 1975) and the health-belief model (Janz & Becker, 1984) in which perceived vulnerability and response efficacy are key elements of coping behavior. Consistent with the affect-as-information perspective (Schwarz & Clore, 1996), a growing body of evidence suggests that subjective estimates of risks are largely based on anticipatory feelings elicited by the threat—a proposition known as the "risk-as-feelings" hypothesis (Loewenstein, Weber, Hsee, & Welch, 2001).

Incidental Affect in Judgment and Decision Making

Although integral affect appears to play a major role in consumers' judgments and decisions, social and consumer psychologists have generally focused instead on incidental affect, especially mood states.

Congruency effects of mood and other forms of incidental affect

Numerous studies have shown that mood states and other forms of incidental affect generally have assimilative (i.e., affect-congruent) influences on evaluations, decisions, and behaviors. Objects are typically evaluated more favorably when the evaluator is in a good mood than when the evaluator is in a bad mood (for reviews, see Forgas, 1995; Gardner, 1985), and more generally when the objects are evaluated in the context of pleasant stimuli than when they are evaluated in the context of unpleasant stimuli. In fact, some of the earliest demonstrations of this phenomenon appeared in marketing. In a pioneering study, Axelrod (1963) observed that, after viewing a depressing television documentary, consumers evaluated a variety of products more negatively than they did before they saw the documentary. These shifts in evaluation were found to be directly related to changes in participants' moods. In another early study, Dommermuth and Millard (1967) found

that consumers, who one week earlier had watched a pleasant movie after tasting a soft drink, evaluated the drink more favorably than consumers who had watched an unpleasant movie. Still, the most widely-cited demonstration of mood-congruency effects is the one published more than 10 years later by Isen, Shalcker, Clark, and Karp (1978), who observed that people who were put in a good mood through a small gift were more willing to participate in a survey and evaluated products more favorably than control subjects who did not receive a gift. In a debated study, Gorn (1982) also observed that people who had seen a pen advertised while pleasant music was playing in the background were more likely to choose this pen than people who had seen the same pen advertised with unpleasant music playing in the background. Similar congruency effects of incidental affect have been observed on a variety of other evaluative and behavioral responses, including judgments of life satisfaction (e.g., Schwarz & Clore, 1983), evaluations of brand extensions (Barone, 2005; Barone, Miniard, & Romeo, 2000; Yeung & Wyer, 2005), evaluations of political candidates (Isbell & Wyer, 1999), judgments of perceived risks (Johnson & Tversky, 1983), and decisions about future consumption episodes (e.g., Gilbert, Gill, & Wilson, 2002; Pham, 1998).

Much of the early evidence about this phenomenon was reviewed 20 years ago by Gardner (1985). Two main types of developments have emerged since. Substantive-oriented investigations have focused on how various aspects of the marketplace can trigger incidental affect that influences evaluations in a congruent fashion. A number of studies have shown that incidental affect elicited by the media context of an ad (TV program or magazine) generally has a congruent influence on consumers' evaluations of the ad but less influence on their evaluations of the advertised brand (e.g., Gardner & Wilhelm, 1987; Goldberg & Gorn, 1987; Mathur & Chattopadhyay, 1991; Murry & Dacin, 1996; Yi, 1990; but see Kamins, Marks, & Skinner, 1991 for different findings). Gift wrapping can also enhance the recipient's evaluation of the gift by elevating the recipient's mood (Howard, 1992). Even the mere action of browsing a series of attractive options may elevate a consumer's mood and result in assimilative effects on subsequent evaluations (Raghunathan & Irwin, 2001). Incidental affect can "transfer" to the target object very rapidly. Morales and Fitzsimons (2007) recently found that a mere physical contact between a new, factory-sealed pack of sanitary napkins (a product many male consumers find disgusting) and another factory-sealed product is sufficient to decrease consumers' intention to try the latter product even though there is no chance of real contamination by the former. An important question is whether this type of spontaneous incidental affect transfer is limited to disgust—as Morales and Fitzsimons (2007) propose—or whether it applies to other types of incidental affect as well (e.g., pride, anger, joy).

More theoretically-oriented investigations have focused on clarifying the process (or processes) that underlie the phenomenon and identifying its boundary conditions. The best-known explanation for the congruency effects of incidental affective states attributes the phenomenon to a differential accessibility of valenced materials in memory under positive versus negative affective states (Isen, Shalcker, Clark, & Karp, 1978). Consistent with other research on the effects and representation of mood states in memory (Bower, 1981), Isen and her colleagues (1978) proposed that positive moods enhance target evaluations by making positive thoughts about the target object more accessible in memory. Consistent with this explanation, they found that participants who were put in a good mood through false success feedback had better memory for pleasant words studied earlier than did participants who were put in a bad mood through false failure feedback. Interestingly, however, there was no difference between the two groups in their memory for unpleasant words, suggesting that the proposed explanation may not equally account for negative mood congruency effects.

Building on the idea that affect is often seen as having information value—an idea known as the "affect-as-information" hypothesis, Schwarz and Clore (1983) proposed a different explana-

tion. They argued that positive and negative affective states have congruent effects on evaluations because, in the course of evaluating objects, people are often inclined to inspect how they feel about these objects—a process known as the “how-do-I-feel-about-it?” heuristic (Schwarz & Clore, 1988; see also Pham, 1998). When relying on this heuristic, people may not always realize that the feelings they experience while evaluating an object may have been affected by preexisting affective states, resulting in assimilation effects. Consistent with this interpretation, Schwarz and Clore (1983) found that respondents, who were in a good mood as a result of being interviewed on a sunny day, reported higher levels of life satisfaction than respondents who were in a bad mood as a result of being interviewed on a rainy day. Importantly, this mood congruency effect disappeared when respondents were made aware of the actual source of their affective state (i.e., the weather). This contingency—known as the *representativeness* principle (Pham, 1998; Strack, 1992)—supports the interpretation that incidental feelings influence evaluations only to the extent that they are perceived to provide information pertaining to the target. In a related study in a consumer context (Gorn, Goldberg, & Basu, 1993), respondents were asked to evaluate a pair of speakers through which music was being played. Incidental affect was manipulated by varying the music being played to be either pleasant or unpleasant. Awareness of the actual source of the feelings was manipulated by asking respondent to rate the music either before they evaluated the speakers (high awareness) or after they had evaluated the speakers (low awareness). As predicted, respondents in the low awareness condition evaluated the speakers more favorably when the music was pleasant than when it was unpleasant—a classic affect congruency effect. In contrast, respondents in the high awareness condition evaluated the speakers equally whether the music was pleasant or unpleasant—consistent with the idea that the congruency effect was driven by the perceived informativeness of the music-induced feelings.

According to the integrative “affect-infusion” model (Forgas, 1995), the two accounts—differential memory accessibility and mood-as-information—are not inconsistent; instead, they operate under different conditions. The differential memory accessibility account is more likely when the person engages in extensive substantive processing such as full and open search in memory, which presumes a certain level of involvement. The mood-as-information account is more likely when the person engages in heuristic processing, which is more common under conditions of low involvement. Consistent with this proposition, it has been found that positive moods have two separate effects in persuasion (Batra & Stayman, 1990; Petty, Schumann, Richman, & Strathman, 1993). Under conditions favoring low elaboration, positive moods have direct assimilative effects on attitudes—a finding consistent with a mood-as-information process. Under conditions favoring high elaboration, the assimilative effects of positive moods on attitudes appear to be mediated by the valence of target-related thoughts during message exposure—a finding consistent with a differential memory accessibility explanation.

Within the mood-as-information account, there is still uncertainty as to the exact locus of the process. In conventional interpretations of the process, feelings are assumed to enter judgments during the formal evaluation stage (Schwarz & Clore, 1988, 1996). However, recent findings suggest that the informative influence of incidental feelings may take place earlier in the process, during an initial appraisal of the object (Yeung & Wyer, 2004).

Moderators of congruency effects of incidental affective states

Factors that increase the reliance on integral feelings in evaluations generally also increase the influence of incidental affect on evaluations. Incidental moods are generally found to have stronger assimilative influences on evaluations when motivation to process information is low (e.g.,

Miniard, Bhatla, Lord, Dickson, & Unnava, 1991; Petty, Schumann, Richman, & Strathman, 1993) and when processing resources are constrained such as under distraction (e.g., Albarracin & Wyer, 2001) or under time pressure (Siemer & Reizenzein, 1998). However, recent studies suggest that higher levels of motivation and ability to process information do not necessarily result in a monotonic decrease of the influence of incidental mood on evaluations. The relationship may sometimes be curvilinear, with stronger influence of incidental mood under moderate levels of motivation and ability (Albarracin & Kumkale, 2003). This is because when motivation and ability to process information are very high, people are likely to recognize that their feelings are incidental and therefore irrelevant for the judgment at hand. Incidental feelings would therefore be discounted. However, when people's motivation and ability to process information is extremely low, they may fail to even notice their incidental feelings. Incidental feelings would therefore not have any influence. There is also consistent evidence that incidental affective states have stronger affect-congruent influences on evaluations when other bases of evaluation are ambiguous (e.g., Bakamitsos, 2006; Gorn, Pham, & Sin, 2001; e.g., Isen & Shalcker, 1982; Miniard, Bhatla, & Sirdeshmukh, 1992), or when people lack expertise with the target domain (Ottati & Isbell, 1996; Srull, 1987).

The affect-as-information hypothesis implies two additional moderators. Consistent with the principle of representativeness mentioned earlier, incidental affective states tend to be more influential when their actual source is not salient (Gorn, Goldberg, & Basu, 1993; Raghunathan, Pham, & Corfman, 2006; Schwarz & Clore, 1983; Siemer & Reizenzein, 1998). This is because, when the actual source of the affective state is salient, people recognize that the affective state is unrelated to (i.e., not representative of) the target and therefore noninformative. Further evidence of a representativeness interpretation of this contingency comes from the finding that, *even when their actual source is salient*, incidental affective states may still influence objectively unrelated judgments and decisions provided that there is a superficial domain similarity between the judgment or decision and the salient origin of the affective state (Raghunathan, Pham, & Corfman, 2006). Inferences of representativeness, we know, are very sensitive to surface similarity (Gilovich, 1981).

Also consistent with the logic of affect-as-information is the findings that, even when people do not recognize that their feelings are truly incidental—that is, even when they assume that their feelings are representative—they do not seem to use them unless they perceive their feelings to be a relevant basis for a specific judgment or decision—a contingency known as the *relevance* principle (Pham, 1998). For example, people are more influenced by their mood when making decisions guided by experiential motives, such as assessing a movie for an evening out, than when making decisions guided by instrumental motives, e.g., assessing the same movie as material for a school project (Pham, 1998). As a result, they are typically more influenced by their moods in decisions involving hedonic products than in decisions involving utilitarian products (Adaval, 2001; Yeung & Wyer, 2004). Mood states have also been found to have greater influence on global judgments of well-being than on more specific judgments such as satisfaction with one's work or housing (Schwarz, Strack, Kommer, & Wagner, 1987). In addition, incidental affective states have been found to be more influential when people make decisions for themselves as opposed to for someone else (Raghunathan & Pham, 1999). Avnet and Pham (2007) recently suggested the idea and found evidence that the reliance on feelings in judgments and decisions may involve a meta-cognitive stage in which people assess whether they *should* use their feelings in a given judgment or decision, and found evidence consistent with this proposition. This meta-cognitive assessment appears to require significant cognitive resources; when resources are insufficient, incidental and integral feelings influence judgments and decisions more indiscriminately. The dual-process, meta-cognitive model proposed by Avnet and Pham (2007) appears to account for a wide variety of findings about the moderators of incidental and integral affect in judgments and decisions.

According to Forgas's (1995) affect-infusion model, incidental affective states have greater assimilative influences on evaluations when the person engages in constructive processing. Evaluations based on nonconstructive processes, such as the retrieval of prior attitudes, are less amenable to affect infusion. For example, Fedorikhin and Cole (2004) found that respondents exposed to a mood-inducing video *prior* to being exposed to a commercial were more influenced by their mood in their evaluation of the advertised product than were respondents exposed to the mood-inducing video *after* viewing the same commercial and forming an initial evaluation of the product. This is presumably because respondents in the mood-before condition had to form their product evaluations "from scratch," which required constructive processing, whereas respondents in the mood-after condition could simply retrieve their previously-formed initial evaluations. More generally, Srull (1987) showed, in a very compelling series of studies, that mood congruent evaluation effects generally require that the incidental mood be experienced at the same time the evaluation is constructed.

Beyond simple valence congruency

Recent findings suggest that incidental mood states do not always influence evaluations in a mood-congruent fashion (i.e., higher evaluations under positive moods than under negative moods). Sometimes, incidental mood states *interact* with the target object to produce evaluations that are *configural*—hence, judgment-specific—rather than strictly mood-congruent. Martin, Abend, Sedikides, and Green (1997) observed that, when asked to evaluate a story that was meant to be happy, participants in a happy mood reported more favorable evaluations than participants in a sad mood. However, when asked to evaluate a story that was meant to be sad, participants in a sad mood reported more favorable evaluations than participants in a happy mood. This finding suggests that people do not literally interpret the valence of their feelings as meaning "goodness" versus "badness." Instead, they interpret the valence of their feelings in light of salient goals and judgment criteria (Pham, 2004). If the criterion is "Is this a good happy story?," feelings of happiness will mean "Yes" and feelings of sadness will mean "No." On the other hand, if the criterion is "Is this a good sad story?," feelings of happiness will mean "No" and feelings of sadness will mean "Yes." Similar configural effects were obtained by Kamins, Marks, and Skinner (1991) who observed that a happy commercial was evaluated more favorably and elicited stronger purchase intentions when presented after a happy TV program than when presented after a sad TV program. In contrast, a sad commercial was evaluated more favorably when presented after a sad program than when presented after a happy program. Somewhat related to the idea of configurality, some findings suggest that mood states increase the weight attached to information that is evaluatively consistent with the mood in product evaluations (Adaval, 2001). According to Adaval (2001), when there is a match between the consumer's affective state and the valence of a piece of information, this information "feels right" and is therefore relied upon with greater confidence.

A growing body of research suggests that incidental affective states also influence target evaluations when the valence of the affective state is held constant. Two main types of findings have been uncovered in this regard. The first set of findings pertain to the effects of incidental emotional arousal. The second set of findings pertain to the differential influence of qualitatively distinct emotional states.

A large number of studies show that, holding valence constant, the arousal component of incidental affective states tends to polarize the evaluation of objects. Evaluations of target objects are usually more extreme under incidental states of high arousal than under incidental states of low arousal (Dutton & Aron, 1974; Foster, Witcher, Campbell, & Green, 1998; Gorn, Pham, & Sin, 2001;

Mattes & Cantor, 1982; White, Fishbein, & Rutsein, 1981; Zillmann, 1971). For example, individuals aroused by contextual factors such as a roller-coaster ride or crossing a high suspension bridge have been found to be more attracted to good-looking individuals of the opposite sex and less attracted to individuals of the same sex (Dienstbier, 1979; Dutton & Aron, 1974; White, Fishbein, & Rutsein, 1981). Similarly, Gorn, Pham, and Sin (2001) observed that consumers who had recently listened to an arousing piece of music (in a supposedly unrelated study) reported more polarized evaluations of an advertisement than consumers who had listened to a less arousing piece of music. Compared to consumers in the low arousal conditions, consumers in the high arousal condition reported more favorable ad evaluations when the ad's affective tone was positive and more unfavorable evaluations when the ad's affective tone was negative. Therefore, incidental states of arousal seem to amplify people's inherent affective and evaluative responses to a target.

Three main explanations have been offered for this phenomenon. According to the cognitive-complexity hypothesis (Paulhus & Lim, 1994), under high arousal, people's representations of target objects become simpler. As a result, the evaluative dimension becomes relatively more salient, causing more polarized judgments. This explanation is consistent with the finding that high arousal induces a selective reliance on information perceived to be more diagnostic in judgment (Pham, 1996). A second explanation is that states of high arousal encourage dominant responses in judgment and behavior (Zajonc, 1965). Because evaluative responses tend to be dominant, high arousal induces polarization (e.g., Allen, Kenrick, Linder, & McCall, 1989). A third explanation, consistent with the affect-as-information hypothesis, is that individuals misattribute their incidental arousal as indicating the strength of their integral affective response to the target, which again results in more polarized evaluations (Pham, 2004). Overall, it seems that all three explanations are viable and may be differentially operative in different situations. For instance, Gorn, Pham, and Sin (2001) suggest that the cognitive-complexity may be more valid under conditions of very strong arousal, whereas the misattribution explanation may be more applicable under conditions of milder arousal. This is because strong arousal states are known to narrow people's focus of attention (Easterbrook, 1959) but are unlikely to be misattributed, whereas milder arousal states may not narrow people's attention but are more likely to be misattributed.

More recent demonstrations of the importance of studying incidental affective states beyond their valence come from the growing body research on the differential effects of distinct emotional states (Lerner & Keltner, 2000, 2001; Lerner, Small, & Loewenstein, 2004; Raghunathan & Pham, 1999; Raghunathan, Pham, & Corfman, 2006; Tiedens & Linton, 2001). In one of the earliest demonstrations, Raghunathan and Pham (1999) found that, in choices between high-risk/high-reward and low-risk/low-reward options, sad individuals consistently favor the former, whereas anxious individuals consistently favor the latter. This is presumably because, even though their states are incidental, sad individuals tend to infer that they have lost something of value (a typical cause of sadness), which activates a goal of reward acquisition that shifts preferences toward high-reward options. In contrast, anxious individuals tend to infer that the situation is uncertain and beyond control (typical causes of anxiety), which activates a goal of risk avoidance that shifts preferences toward low-risk options. Similarly, Lerner, Small, and Loewenstein (2004) found that incidental states of sadness reverse the classic endowment effect, that is, the tendency to place a higher value on objects that are already in our possession compared to identical objects that not in our possession. In contrast, incidental states of disgust eliminate the endowment effect. According to the authors, this is because sadness creates a motivation to change the current situation, which increases the willingness to pay for objects that are not in our possession (higher purchase prices) and also increases the willingness to sell objects that currently are (lower selling prices). In contrast, disgust triggers an impulse to get rid of objects that are currently in our possession (lower

selling prices) without necessarily distorting the value of objects that are not in our possession (unchanged purchase prices). Tiedens and Linton (2001) also observed that respondents made predictions with greater confidence when under states of disgust or happiness than when under states of fear or hopefulness. This is presumably because both disgust and happiness typically arise in situations appraised as certain (e.g., witnessing something repulsive or receiving very good news), whereas fear and hope typically arise in situations appraised as uncertain (e.g., going up for tenure). These findings are generally consistent with an affect-as-information process in which the information conveyed by affective states comes from the typical appraisal content of these affective states (Pham, 2004). Further evidence that these effects are driven by an affect-as-information process comes from the finding that they tend to disappear when the true source of the affective state is made salient (Raghunathan et al. 2006, Experiment 1), unless there is a surface domain resemblance between the source of the incidental affective state and the target decision (Raghunathan et al., 2006, Experiment 2).

Effects of incidental affect on judgment and decision processes

In addition to shaping the *content* of consumer's judgments and decisions, incidental affective states can also influence the *process* through which these judgments and decisions are made. The nature of these influences seems to depend on (a) the intensity of the affective state, (b) the valence of the affective state, and (c) the appraisal content of the emotional state.

Because high arousal is known to impair working memory capacity (S. Darke, 1988a; Humphreys & Revelle, 1984), it is generally believed and often observed that states of high emotional arousal interfere with people's ability to reason and make judgments and decisions. For example, compared to nonanxious participants, anxious participants have been observed to (a) take longer to verify logical inferences (S. Darke, 1988b), (b) scan alternatives in a more haphazard fashion and select options without considering every alternative (Keinan, 1987), (c) commit more errors in analogical problems (Keinan, 1987; Leon & Revelle, 1985), and (d) process persuasion arguments less thoroughly (Sanbonmatsu & Kardes, 1988; but see Pham, 1996 for a different interpretation). It should be noted, however, that most of these findings pertain to the effects of high anxiety. It is therefore not clear whether they generalize to other types of emotional arousal such as intense joy, anger, or pride. It should also be noted that states of intense emotional arousal can benefit judgment processes in at least one respect. Compared to states of lower arousal, states of high emotional arousal seem to increase the selective relative reliance on diagnostic information in persuasion and judgment in general (Pham, 1996). This explains the finding that incidental states of high anxiety do not decrease message elaboration when the message is related to the source of anxiety (Sengupta & Johar, 2001).

Interestingly, acute emotional states characterized by low arousal also appear to interfere with people's judgment abilities. A number of studies indicate that chronic depression interferes with people's reasoning and ability to engage in effortful processing in judgment (Conway & Giannopoulos, 1993; Hartlage, Alloy, Vazquez, & Dykman, 1993; Silberman, Weingartner, & Post, 1983). Overall, it appears that intense emotional states, regardless of their associated level of arousal, generally interfere with people's reasoning and judgment processes. One exception, however, relates to the ability to prioritize diagnostic versus nondiagnostic information, which seems to increase under states of high emotional arousal (Pham, 1996).

Milder incidental affective states, such as moods, can also influence people's judgmental processes. Compared to individuals in a neutral mood, individuals in a good mood have been found to (a) categorize objects more broadly (Isen & Daubman, 1984; Isen, Niedenthal, & Cantor, 1992), (b)

generate more creative answers in response-generation tasks (Greene & Noice, 1988; Hirt, Melton, McDonald, & Harackiewicz, 1996), (c) perform better in problem-solving tasks that require ingenuity (Greene & Noice, 1988; Isen, Daubman, & Nowicki, 1987), and (d) solve a multi-attribute decision problem more efficiently (Isen & Means, 1983). These and other findings have been interpreted as showing that positive moods have generally beneficial effects on reasoning, problem solving, judgment, and decision making (Isen, 2001).

However, a number of studies suggest that positive moods lead to poorer reasoning performance in a variety of respects. Positive mood individuals are more likely to commit the “fundamental attribution error” of overestimating the degree to which others’ behaviors are driven by their personal disposition as opposed to by situational factors (Forgas, 1998). Positive mood participants have also been found to perform more poorly in deductive reasoning tasks (Oaksford, Morris, Grainger, & Williams, 1996) and exhibit more intransitive preferences (Fiedler, 1988). Numerous studies also indicate that positive moods generally decrease the depth with which people process substantive information in persuasion and attitude formation (Batra & Stayman, 1990; Bless, Bohner, Schwarz, & Strack, 1990; Bless, Mackie, & Schwarz, 1992; Mackie & Worth, 1989; Worth & Mackie, 1987). Positive mood individuals seem to rely instead on global knowledge structures and internal cues including scripts (Bless, Schwarz, Clore, Golisano, & Rabe, 1996), stereotypes (Bodenhausen, Kramer, & Suesser, 1994), and judgmental heuristics such as the ease of retrieval (Ruder & Bless, 2003). Overall, positive moods seem to have mixed effects on people’s reasoning and judgment processes. On the one hand, they seem to promote greater flexibility and creativity in problem solving; on the other hand, they seem to promote a more top-down, less data-driven, and less thorough mode of processing. Recent studies by Adaval (2003) suggest that one consequence of this more top-down form of processing is that positive moods polarize the evaluative impact of judgment inputs involving preexisting knowledge structures (e.g., schemata, stereotypes, categories, brands, etc.). Adaval’s (2003) studies show that, under positive mood, brand names (and their associated knowledge structures) have greater influence on product evaluations than under negative mood. Specifically, products from popular brands are evaluated more favorably under positive mood than under negative mood, whereas products from unpopular brands are evaluated less favorably under positive mood than under negative mood.

Negative moods, especially those of sad nature, have generally been found to have effects that mirror those described above. Compared to neutral and pleasant moods, sad moods have been found to increase the care with which people process substantive information in persuasion (Bless, Bohner, Schwarz, & Strack, 1990; Sinclair, Mark, & Clore, 1994), decrease the reliance on general knowledge structures such as scripts and stereotypes (Bless, Schwarz, Clore, Golisano, & Rabe, 1996; Bodenhausen, Kramer, & Suesser, 1994), increase the ability to estimate covariation from scatter plot data (Sinclair & Mark, 1995), reduce the susceptibility to halo effects (Sinclair, 1988), reduce fundamental attribution errors (Forgas, 1998), and increase the transitivity of preferences (Fiedler, 1988). Overall, temporary sad moods seem to trigger a more systematic, data-driven, and analytical form of reasoning. One possible explanation, also based on the affect-as-information hypothesis, is that sad moods signal to the individual that the situation is problematic and therefore requires a more vigilant form of processing, whereas good moods signal that the situation is benign and allows a more nonchalant form of processing (Schwarz, 2002).

It should be noted, however, that not all negative moods trigger a vigilant form of processing. States of anger or disgust seem to *decrease* the depth of processing and increase the reliance on stereotyping and other heuristic cues, apparently because these states trigger a sense of certainty (Bodenhausen, Sheppard, & Kramer, 1994; Tiedens & Linton, 2001).

It should also be noted that negative moods do not always increase task effort and positive moods always decrease it. Martin, Ward, Achee, and Wyer (1993) asked respondents in a positive or negative mood to perform various tasks under one of two sets of instructions. One group was asked to keep working until they were satisfied with their performance. The other group was asked to keep working until they no longer enjoyed the task. When instructed to keep working until they were satisfied with their performance, respondents in a negative mood worked longer than those in a positive mood (a result consistent with the typical finding that negative mood leads to more careful processing compared to positive mood). However, when instructed to keep working until they no longer enjoyed the task, the effect reversed: respondents in a negative mood stopped *sooner* than those in a positive mood. Apparently, when the instruction was to keep working until satisfied with the performance, a negative mood was construed as dissatisfaction with one's effort, producing greater perseverance, whereas a positive mood was construed as satisfaction with one's effort, triggering an early stop. In contrast, when the instruction was to keep working until the task was no longer enjoyed, a negative mood was construed as the task being not fun, producing an early stop, whereas a positive mood was construed as the task being fun, producing perseverance. This interpretation, known as the "mood-as-input" hypothesis (Martin, Ward, Achee, & Wyer, 1993), illustrates a broader principle about the informative role of feelings in judgments. The same feelings can have very different interpretations depending on the question that people are asking themselves (Pham, 2004). The information value of the feelings lies not so much in the feelings themselves as in the interaction between these feelings and the questions that people are trying to answer when consulting their feelings, which depends on situational demands and more generally on the person's currently active goals.

Effects of mood states on risk-taking

A number of studies indicate that, compared to neutral moods, positive moods promote risk-taking when the stakes and chances of loss are low but risk-avoidance when the stakes and chances of loss are high (Arkes, Herren, & Isen, 1988; Dunegan, Duchon, & Barton, 1992; Isen & Geva, 1987; Isen, Nygren, & Ashby, 1988; Kahn & Isen, 1993; Nygren, Isen, Taylor, & Dulin, 1996). For example, Arkes, Herren, and Isen (1988) observed that, compared to control participants, participants who received a small gift were willing to pay more for lottery tickets, especially when the prize level and probability of winning were high—indicating greater risk-seeking under positive mood in situations with only upsides. However, participants who received a small gift were also more willing to pay more to insure against a variety of losses, especially when potential losses were high—indicating greater risk-aversion under positive mood in situations characterized by downsides. Kahn and Isen (1993) observed a similar pattern in the effects of positive mood on variety-seeking. They found that, compared to control participants, participants who were in a good mood sampled a greater variety of products such as crackers, soups, and chips, unless the choice set included items expected to taste poorly. Again, positive mood appeared to promote risk-seeking in benign settings and risk-avoidance in settings involving potential risk. According to Isen and her colleagues, when the decisions entail low risks and stakes, positive mood individuals tend to have more optimistic (mood-congruent) expectations about the outcomes and, therefore, take greater risks compared to neutral mood individuals. However, when the stakes are high and the potential for losses significant, positive mood individuals become risk-averse because they want to maintain their positive affective state, which a loss would disrupt (e.g., Isen, Nygren, & Ashby, 1988; Kahn & Isen, 1993) as will be discussed further in the section on affect regulation.

The effects of negative affective states on risk-taking are not as clear. Several studies indicate that negative emotional states accompanied by strong arousal increase risk-seeking (Fessler, Pillsworth, & Flamson, 2004; Leith & Baumeister, 1996; Mano, 1992, 1994). For example, Leith and Baumeister (1996) found that angry participants and participants anticipating impending embarrassment were more likely to choose an economically inferior “long-shot” gamble with a low probability of obtaining a larger amount of money and a high complementary probability of enduring some stressful noise, over a superior “safe-bet” gamble with a higher probability of obtaining a smaller amount of money with a low probability of enduring the stressful noise. Sad participants, however, did not exhibit this bias. Fessler, Pillsworth, and Flamson (2004) also found that anger triggered more risk-seeking in gambling, especially among men. Similarly, Mano (1994) found that intense emotional arousal increased people’s willingness to pay for lotteries and decreased their willingness to pay for insurance; that is, increased risk-taking for both potential gains and potential losses.

However, other findings indicate that people’s attitude toward risk under negative affective states is not just a function of the level of arousal associated with the affective state, but also a function of the appraisal content of the affective state (Lerner & Keltner, 2001; Raghunathan & Pham, 1999). For example, as mentioned previously, in choices between low-risk/low-reward and high-risk/high-reward options, anxious individuals tend to prefer the former, whereas sad individuals tend to prefer the latter (Raghunathan & Pham, 1999; Raghunathan, Pham, & Corfman, 2006). The consistent risk-aversion exhibited by anxious individuals in these studies seems inconsistent with Leith and Baumeister’s (1996) proposition that high-arousal emotion lead to risk-seeking. In fact, other studies show that, when the level of arousal is held constant, anxiety *reduces* risk-seeking (Mano, 1992, 1994). According to Raghunathan and Pham (1999), this is because anxiety, which is typically associated with situations of low control and high uncertainty, activates a goal of risk and uncertainty minimization, whereas sadness, which is typically experienced in response to the loss of a source of reward, activates a goal of reward maximization. Similarly, Lerner and Keltner (2001) observed that, even though fear and anger are both high-arousal negative emotions, fear tends to trigger risk-aversion, whereas anger tends to trigger risk-seeking. This is apparently because fear is typically associated with situations of uncertainty and low control, whereas anger is typically associated with situations of certainty and high control. It has also been found that disgust, another high arousal emotion, decreases risk-seeking in gambling among women (Fessler, Pillsworth, & Flamson, 2004).

In summary, it appears that intense negative emotions do not have a uniformly positive effect on risk-seeking. High emotional arousal seems neither necessary, nor sufficient to explain risk-seeking under negative emotions. The effects of negative emotions on risk-seeking appear to depend not only on the level of arousal associated with the emotional state, but also on complex interactions between the goals activated by the emotional state and the nature of the risks to be taken. This may partly explain why a meta-analysis of published studies relating chronic states of anger, sadness, and anxiety to risky sexual behavior (Crepaz & Marks, 2001) found virtually no correlation ($r = .05$).⁵

Task-Related Affect in Judgment and Decision Making

The *process* of making judgments or decisions may *itself* induce feelings and emotions. We call this type of affect *task-related affect*. A common task-related affect is the unpleasant feelings that consumers often experience when they have to trade off important attributes whose values are negatively correlated across choice options. Consider a choice between prospective apartments. Apartment A is much roomier, but is located in a bad neighborhood; whereas Apartment B is much smaller, but located in a great neighborhood. It has been found that the aversive emotional

experience of having to make trade-offs across important attributes often leads consumers to prefer avoidant options such as choosing the status quo or deferring the choice (Luce, 1998). This avoidant behavior seems to be a deliberate attempt by the consumer to mitigate the unpleasant feelings by eschewing the trade-offs altogether. This avoidant behavior is attenuated under situations of cognitive load, which reduces the aversiveness of the trade-offs by making them less apparent (Drolet & Luce, 2004). Another way in which consumers attempt to deal with the emotional aversiveness of difficult decisions is to resort to simpler, heuristic decision strategies such as processing attribute-by-attribute (as opposed to alternative-by-alternative) and invoking dominance relations (Luce, 1998; Luce, Bettman, & Payne, 1997). It has also been found that, when trade-offs are emotional, consumers tend to place greater weight on the relative quality of the options, such as the relative safety of two cars, rather than on their relative resource requirements, e.g., the relative price of the cars (Luce, Payne, & Bettman, 1999).

Task-related affect, in the form of stress, can also be induced by giving decision makers some time pressure and the impression of being monitored during the decision (Stone & Kadous, 1997). Unlike the manipulations based on trade-off difficulty mentioned above, this method presents the advantage of holding information about the options constant. Stone and Kadous (1997) found that, under task-related stress, decision makers tend to use a “scanning” strategy of quickly but indiscriminately examining available information, which may increase choice accuracy in easy choice environments but decrease choice accuracy in difficult choice environments.

Another common type of task-related affect in decision making is the unpleasant feeling of having to forego attractive options. In a choice among a Mercedes-Benz S550, a BMW 750i, and an Audi A8, for example, choosing the Mercedes-Benz also means forfeiting the BMW and the Audi—a classic approach, approach conflict that may be emotionally stressful. Dhar and Wertenbroch (2000) found that the emotional discomfort of forgoing an option is greater when the option is primarily hedonic, such as a fun sports car, than when the option is primarily utilitarian, such as a functional minivan. It has also been found that the more consumers deliberate about their choices, the more they become emotionally attached to the options, which leads to decision-related discomfort (or cognitive dissonance) once one option has been chosen (Carmon, Wertenbroch, & Zeelenberg, 2003).

A particularly important outcome of task-related affect is the transfer of that affect onto the valuation of the chosen alternative. Just like incidental affective states, task-related affective responses may be misconstrued as reflecting genuine integral affective responses to one of the options—a phenomenon again broadly consistent with the affect-as-information framework (Schwarz, 1990; see also Pham [2004] for a review). For example, Garbarino and Edell (1997) found that reducing the effort involved in selecting an alternative (i.e., making a task less unpleasant) can increase the price respondents are willing to pay for that alternative. The transfer of task-related affect onto the valuation of alternatives underlies a growing body of research on the “value-from-fit” hypothesis (Higgins, 2000). According to this hypothesis, a fit between the manner in which a decision is made and the current orientation of the decision maker can produce pleasant task-related feelings of “being right,” which can then be (mis)attributed to a chosen object, enhancing its perceived value (e.g., Avnet & Higgins, 2003, 2006; Higgins, Idson, Freitas, Spiegel, & Molden, 2003). This finding also illustrates the close connection between affect and motivation, discussed next.

AFFECT AND MOTIVATION

The study of affect and the study of motivation have traditionally been interrelated (Young, 1961). Motivation and emotion share the same Latin root, *movere*, which means “to move.” Affective states are said to stimulate action tendencies (Elster, 1999; Lazarus, 1991), action readiness (Frijda,

1986; Lang, 1995), and goal shifts (Oatley, 1992; Simon, 1967). Some researchers argue that affective states function as part of a superordinate program that directs motivational priorities and goal choice (Cosmides & Tooby, 2000) and motivates individuals to pursue specific goals. The interaction between motivation and affect is bidirectional: (1) affective states activate goals; and (2) goal pursuit (achievement, blockage, progress rate, etc.) triggers specific affective reactions (Carver, Lawrence, & Scheier, 1996). Although both directions of influence are of substantial theoretical interest, in this chapter we focus on the affect-to-motivation direction because the motivational consequences of affect have been studied more extensively.

In general, affective motivation relies on affect's informational role. As previously described, Schwarz and Clore's (1983) seminal work represents the cornerstone of the informational tradition associated with experienced affective states. When asked to assess their life satisfaction, many respondents in this study misattributed their weather-induced feelings to the unrelated judgment at hand. Usually overlooked in the literature is the fact that the study also asked individuals to assess their "desire to change." When asked this question on a rainy (versus sunny) day, individuals reported a stronger desire—hence, a stronger motivation—to change. Schwarz and Clore's (1983) findings thus demonstrate not only the informational role of affect, but also its *motivational* consequences.

Strength of the Signal, Approach, and Avoidance

When affect deviates from a homeostatic range, this signals that something has altered the actual or anticipated state of the environment, thus increasing the likelihood of unanticipated negative or positive consequences, such as those related to threats or safety. The strength of this signal is a direct function of how much affect deviates from its normal homeostatic range. However, the relation is not symmetric. Cacioppo, Gardner, and Berntson (1999) suggest that when the affective signal is at zero (in terms of motivational input), there is a weakly positive approach tendency (in terms of motivational output)—a phenomenon, the authors call the "positivity offset." In other words, at very low levels of affective activation, the motivation to approach is stronger than the motivation to avoid. Cacioppo, Gardner, and Berntson (1999) further suggest that the evolutionary function of the positivity offset is to increase the organism's tendency to approach novel objects and stimuli in neutral environments. In the absence of such a motivation to explore, organisms would learn little about novel or neutral-appearing environments and their potential reward value.

However, there is also a well documented negativity bias in human behavior (Baumeister, Bratslavsky, Finkenauer, & Vohs, 2001), which cannot be fully explained by the greater diagnosticity (e.g., reduced frequency and greater information value) of negative information (Skowronski & Carlston, 1989). Ito, Cacioppo, and Lang (1998) analyzed affective responses to hundreds of slides from the International Affective Picture System (Lang, Bradley, & Cuthbert, 1997). In one analysis, subjective ratings of positivity of the mostly pleasant slides, and subjective ratings of negativity of the mostly unpleasant slides, were modeled as a function of the level of arousal elicited by each slide. Not surprisingly, both relationships were positive: pleasant slides were rated more positively as they arousal levels increased; and unpleasant slides were rated more negatively as they arousal levels increased. More importantly, ratings of positivity had a *higher intercept* than ratings of negativity. When arousal was very low, pleasant slides were rated more positively than unpleasant slides were rated negatively—a finding consistent with a positivity offset. On the other hand, the slope of the negativity ratings was steeper than that of the positivity ratings—a finding consistent with the negativity bias. Therefore, at low levels of activation, positive stimuli have a greater impact on affective responses (and presumably behavior) than negative stimuli do. However, at higher

levels of activation, negative stimuli have greater impact than positive stimuli do. (See Crites, Fabrigar, & Petty, 1994; Taylor, 1991; Wojciszke, Brycz, & Borkeu, 1993 for supportive findings.) A recent study by Dijksterhuis and Aarts (2003) provides additional support for these propositions. Respondents were exposed subliminally to both positive and negative words and asked to guess whether the words were positive or negative. Performance was better than chance for negative words, but not for positive words. This finding suggests a lower threshold for unconscious negative affect to become accessible. According to Cacioppo, Gardner, and Bernsten (1999), the positivity offset fosters useful exploratory behavior. However, because exploration can also have aversive consequences, and it is more difficult to reverse adverse consequences, natural selection may have favored a capacity to respond more strongly to, and withdraw from, proximate negative stimuli. This duality of function may have contributed to distinguishable approach and avoidance mechanisms mobilizing the individual toward immediate action.

A similar analysis by Lang and his colleagues (Lang, Bradley, & Cuthbert, 1990, 1992) supports the distinction between an aversive/defensive/withdrawal system and an appetitive/approach system, each with distinct patterns of neural activity. The greater the appetitive input, the stronger the activation of positivity and approach forces; the greater the aversive input, the stronger the activation of negativity and avoidance forces. Cacioppo & Berntson's (1994) evaluative space formulation allows for a co-activation of both systems, resulting in either directional action (approach or avoidance), indifference (low activation of both positivity and negativity), or ambivalence (high activation of both positivity and negativity).

However, physical behavior is facilitated by integrating the output of these dual processes and resolving any co-activation of opposing forces to express the dominant tendency and inhibit the weaker tendency. This is evident in postural support reactions, balance, and dynamic motor adjustments and implies a neurological substrate for central bivariate control (i.e., coactivity) of flexors and extensors despite the fact that outcomes are physically constrained into bipolar molar responses. Co-activation is also consistent with findings indicating that central mechanisms for reward and aversion can be independently manipulated, since this implies a fundamental dissociability of related brain systems. Further research should examine whether this separability can help explain why initiatives designed to produce positive affective responses do not necessarily overcome negative biases and so-called "implicit attitudes" (see Sarason et al., 1993; Schofield, 1991). One important implication of co-activation is that an increase in the intensity of either positive or negative valence can transform inaction into action, perhaps leading a person to take risks that had restrained behavior, as when fear of unsafe sex or cigarette addiction are overcome by either added momentary attractiveness or the perception of reduced likelihood or severity of consequences (Bolton, Cohen, & Bloom, 2006).

Broadly speaking, then, affective signals direct attention to both environmental and personal factors (particular current actions) that seem likely to alter consequences. This also fosters, or mitigates, energy and resource expenditure for both mental and behavioral activity. This "effort to perform" response is one of the accounts used to explain why people may devote more time or higher levels of thought in scrutinizing the information available (versus relying on heuristics) when experiencing a negative (versus positive) affective state (Schwarz, 2002).

While goal achievement and harm avoidance are particularly responsive to affective signals, hedonism (the emphasis on feeling good) can be a default goal. For example, psychological theories have traditionally stressed the dynamic tension between task success and accuracy motivations, on the one hand, and ego-bolstering and feeling good on the other (e.g., Lazarus & Folkman, 1984). Of particular interest in research on affect is the notion that a currently negative affective state can motivate individuals to pursue a short-term hedonistic objective, whereas a positive affective state

can motivate individuals to protect the current given state. People are not necessarily spending more effort in order to perform well, but are selectively choosing the stimuli that will regulate their current affective states.

Affect Regulation

In the last two decades, affect regulation has received special attention in the literature (Forgas, Johnson, & Ciarrochi, 1998; Gross, 1998; Larsen, 2000; Zillmann, 1988a, 1988b). For our purposes, affect regulation corresponds to people's spontaneous (conscious or unconscious) attempt to intensify, attenuate, or maintain a given affective state, usually in the short-term. It incorporates related constructs, such as mood regulation (Erber & Erber, 2001; Larsen, 2000), negative state relief (Cialdini, Darby, & Vincent, 1973), mood management (Forgas, Johnson, & Ciarrochi, 1998; Wegener & Petty, 1994; Zillmann, 1988b), mood maintenance (Clark & Isen, 1982; Isen, 1984), emotion regulation (Gross, 1998), and coping (Lazarus, 1991). Although biological drives such as hunger and thirst (Buck, 1999) could also be incorporated within the affect regulation umbrella (Gross, 1998), they are beyond our scope of analysis.

As a basic psychological mechanism, Andrade (2005) proposes that affect regulation rests on three principles: dynamic affect, conditional hedonism, and affective signaling (see also Cohen & Andrade, 2004). *Dynamic affect* represents individuals' projected discrepancy between feelings at two points in time, that is, what they feel now and what they could feel in the future as a result of the cognitive or behavioral activity. This gap captures the motivational property of affect in guiding information processing, judgment, and decision making. Coupled with a basic hedonistic assumption, when no contingencies are available in the environment, affect regulation predicts that people in negative affective states will be the most likely to engage in cognitive or behavioral activities in anticipation of the mood-lifting consequences of such enterprises, whereas people in a positive mood will be the most likely to avoid thoughts and actions in anticipation of the mood-threatening consequences associated with them. In short, as a result of a dynamic analysis, people are likely to move toward the goal of a more positive affective state when they feel bad, as well as to protect a current affective state when they feel good. At the core of the dynamic affect principle is the idea that people's intuitive theories about the affective changing properties of the forward-looking cognitions or behaviors are critical determinants of the impact of affect regulation. For affect regulation to guide responses, people must intuitively believe that the forthcoming thoughts and/or actions will regulate a current state upward or downward (e.g., Manucia, Baumann, & Cialdini, 1984; Tice, Bratslavsky, & Baumeister, 2001).

Although individuals are predisposed to improve a negative affective state and/or protect a current positive affective state, there are circumstances in which internal or environmental contingencies convince them to follow a different route (e.g., Erber, Wegner, & Theriault, 1996). *Conditional hedonism*, therefore, implies that both upward and downward affect regulation, and negative and positive mood maintenance, represent potential affect regulation strategies, depending on competing goals available in the environment. If a performance goal overcomes a short-term hedonistic goal, the former may be preferred (e.g., Cohen & Andrade, 2004).

Finally, stronger, more accessible affective signals lead to clearer assessment of the discrepancy between current and expected affective states and the appropriateness of the actual state. As polarized affective states produce stronger signals compared to more neutral feelings, affect regulation should lead to stronger impacts when people experience positive or negative affect versus neutrality (e.g., Cohen & Andrade, 2004; Wegener & Petty, 1994). If one's current affective state is not salient, a discrepancy is less likely to be identified, minimizing the impact of affect regulation on thoughts

and behavior. Not only accessibility, but also diagnosticity should play a role. Consistent with the affect-as-information hypothesis (Schwarz & Clore, 1983; Pham, 1998, 2004), calling for the diagnosticity of the current affective state into question can undo efforts to regulate affect. For example, if sad consumers suddenly realize that they are buying comfort food in a supermarket in an attempt to regulate their current negative feelings, having them properly attribute their feelings may mitigate their affect-regulation-driven impulse-buying motives, unless the comfort food seems somewhat related to the cause of sadness (Raghunathan, Pham, & Corfman, 2006). However, at least two other aspects must be considered. First, a normative assessment of the affect-behavior relationship is required. One must believe that the ongoing/forthcoming cognitive or behavioral activity that results from the transient feeling state is *inappropriate* (e.g., “I shouldn’t be buying that much just because I feel sad today”). This may not be always the case. For instance, many consumers report going shopping in a *deliberate* attempt at affect regulation (Babin, Darden, & Griffin, 1994; Mick & Demoss, 1990). Trying to regulate current negative feelings through a shopping experience may sometimes be perceived as an appropriate and effective reaction. In that case, to highlight negative affect as a potential cause for the behavior may intensify rather than mitigate the impact of affect regulation on behavior. Second, the consumer must have the *skills* to stop the ongoing action or avoid the forthcoming action. Behavioral reactions driven by current affective states are sometimes much more difficult to control than one would expect, even when the person consciously knows that his/her behavior is inappropriate (e.g., “I shouldn’t be doing this, but I can’t control myself”; Loewenstein, 1996). How perceived appropriateness and skills moderate affect regulation motives is an important issue that remains to be examined in this literature.

Affect Regulation Effects on Information Processing

Affective states have been shown to produce changes in attention, recall, and processing style via affect regulation. Most research has so far been conducted in the psychology literature (for a review, see Gross, 1998), although consumer researchers have demonstrated growing interest in the topic (e.g., Keller, Lipkus, & Rimer, 2003; Meloy, 2000).

Attention

Standard information processing theory assumes limited cognitive resources and therefore selective processing. Thus, at the perceptual level, decisions have to be made as to what pieces of information one attends to. Incidental (dispositional or situational) and integral affect have both been shown to influence such perceptual decision processes via affect regulation (Krohne, 2003). First, one can simply avoid the threatening stimulus when there is no reason to pay attention to it. For instance, MacLeod and Mathews (1988) observed that states of high anxiety (as assessed 1 week before an exam) shifted attention toward exam-relevant threat words, suggesting vigilance, whereas, states of low anxiety (as assessed 12 weeks before the exam) shifted attention away from exam-relevant threat words, suggesting avoidance. Second, recent evidence suggests that negative stimuli not only capture but also hold people’s attention (Fox, Russo, Bowles, & Dutton, 2001; Putman, Hermans, & van Honk, 2004). Thus, those who display stronger upward affect regulation tendencies should demonstrate faster disengagement skills. Mather and Carstensen (2003) adopted such a rationale to provide further evidence that upward affect regulation skills improve with age. After being presented with pairs of negative and neutral faces, older adults responded faster to a subsequent dot probe that appeared on the opposite side of the negative (versus neutral) face. This attentional bias did not emerge among younger adults. Finally, it has been suggested that affect

regulation directs people's attention not only away from negativity, but also toward relieving cues (Derryberry & Tucker, 1994).

Memory

Feelings not only influence what individuals encode but also how much they store and retrieve (Blaney, 1986). Initial evidence supported mood congruent recall. However, as data accumulated, the phenomenon has been shown to be more robust on the positive side of the affective spectrum—i.e., people in a positive mood were more likely to recall positive events than those in a negative mood were to recall negative events (Bower & Forgas, 2000). Isen (1984) suggested that affect regulation could explain this asymmetry. Negative feelings can sometimes encourage the recall of positive information because people are naturally motivated to feel better. Considerable evidence supports Isen's initial proposition (Erber & Erber, 1994; McFarland & Buehler, 1997, 1998; Parrott & Sabini, 1990; Rusting & DeHart, 2000; Sedikides, 1994; Smith & Petty, 1995). However, boundary conditions do exist. The impact of upward affect regulation is weaker among chronically sad individuals. Josephson and colleagues (1996) found that whereas a negative affect manipulation increased mood-incongruent recall among nondysphoric individuals, the effect dissipated among chronically dysphoric participants. Moreover, further evidence showed that when explicitly asked to recall more positive autobiographical memories, nondysphoric and dysphoric participants were equally capable of accomplishing the task. However, only nondysphoric participants felt better afterwards (Joormann & Siemer, 2004). These results suggest that recall of positive memories is reduced among dysphoric individuals, not because of cognitive inability but probably because such memories are not perceived as an affect regulation opportunity within this group. Consistent with the *dynamic affect* assumption described above, if the cognitive or behavioral activity is not perceived as mood-lifting, or mood-threatening, affect regulation will be less likely to influence information processing.

Whereas the impact of mood incongruent recall has been more consistently explored within the negative affect realm, there has been some evidence suggesting that positive affect can also trigger affect regulation and biased recall. Parrott and Sabini (1990) showed in natural (Studies 1 and 2) and laboratory (Studies 3 and 4) settings that not only did subjects in a negative mood recall more positive events, but that subjects in a positive mood were also more likely to recall negative events. The authors do not make strong claims as to the reason for mood incongruent recall but speculate that people may be engaging in spontaneous, and probably unconscious, downward mood regulation. According to the *conditional hedonism* assumption described above, positive mood attenuation is possible. However, this usually happens when competing goals—including the need for accuracy and objectivity—are made available. In this case, individuals have a reason to give up their short-term happiness in exchange for better task performance and subsequent pleasantness (e.g., Cohen & Andrade, 2004; Erber, Wegner, & Theriault, 1996).

Affect regulation motivates people to protect positive affect sometimes at the expense of performance. However, when the task at hand produces harmful effects in the long run, performance becomes a major concern (a stronger competing goal) and positive affect can serve as a psychological buffer to help individuals cope with the negativity in the environment. That is the rationale behind Trope and colleagues' mood-as-resource hypothesis and findings (Raghunathan & Trope, 2002; Trope & Neter, 1994; Trope & Pomerantz, 1998). They showed that when information is highly self-relevant, those in a positive, hence bolstered, mood were more likely to select and/or recall negative information. For example, heavy consumers of caffeine in a positive (versus negative) mood recalled more pieces of negative information, as compared to positive information,

about caffeine consumption. However, a positive mood did not enhance the recall of the negative information for light consumers of caffeine. Although it is not clear whether this effect is mediated solely by motivation (i.e., goal shift from happiness in the short-term to happiness in the long-term) or also by skill (i.e., higher cognitive capacity to deal with information), the mood-as-a-resource hypothesis can, under certain circumstances, account for mood incongruent recall by people experiencing positive affect.

Processing style

Some authors have suggested that the motivational influence of affect may not only represent a stronger or weaker desire to process the information per se, but also corresponds to a deliberate attempt at affect regulation (Ambady & Gray, 2002; Forgas, 1998). People experiencing negative affect may be pursuing more systematic and effortful processing in an attempt to improve their negative affective state (Clark & Isen, 1982; Forgas, 1991a, 1991b; Sedikides, 1994), whereas those in a good mood may spend less effort in an attempt to protect their current affective state (Clark & Isen, 1982; Isen, 1984). According to the main implication of the *dynamic affect* principle, the impact of affect regulation on the quantity and quality of information processing is highly contingent on the expected affective changes associated with the task (i.e., its mood-lifting or mood-threatening characteristics). For instance, if people's unbiased assessment of the attitude object when in a bad mood represents an effective mood-lifting opportunity (e.g., "I will feel happier if do not rely on stereotypes"), sad people should be less likely to rely on such heuristics. Similarly, if the effort spent processing the information represents a mood-threatening experience (e.g., "If I think too much about it, I will feel bad"), happy people should be more likely to rely on heuristics. Although plausible, one of the major challenges in this line of research is to isolate the impact of the affect regulation motive from other mediating processes, such as affect-as-information and the role of confidence. For instance, when a sad person processes a message more carefully than a happy person, is it due to (1) a basic inner signal ("Threatening environment, be careful!"), (2) a lower level of confidence about his/her level of accuracy ("I'm not yet ready to make up my mind."), and/or (3) an affect regulation strategy ("If I accomplish this task accurately, I will feel much better!"). Moreover, these accounts may overlap, which makes claims about affect regulation effects on information processing even more challenging. For affect regulation to operate and bias thought and behavior, individuals must perceive the usually short-term, mood-lifting or mood-threatening cues associated with the upcoming activity. In the information processing world, people have to recognize that the *effort or performance consequences* will regulate their affective state upwards when they feel bad; whereas it will attenuate their affective state when they feel good. Further research is needed to tackle this issue.

Affect Regulation in Judgment and Decision Making

The impact of affect regulation on decision making has drawn increasing attention. Consumers often take the affective consequences of decisions (buy vs. not buy; shop vs. not shop; buy product A vs. B) into account. In the past 25 years, the results converge with the affect regulation principles described above.

Negative affect and affect regulation

An overview of different research streams shows that people experiencing negative affect are more willing to make behavioral choices that will lead to more positive feelings. Thus, they will engage

in a wide variety of behaviors in an attempt to change the current feelings. Documented regulation behaviors include watching comedies (Weaver & Laird, 1995; Zillmann, 1988a, 1988b), listening to uplifting music (Cohen & Andrade, 2004; Knobloch & Zillmann, 2002), eating (Grunberg & Straub, 1992; Tice, Bratslavsky, & Baumeister, 2001), exercising (Hsiao & Thayer, 1998), acting in an aggressive way toward others (Bushman, Baumeister, & Phillips, 2001), reading uplifting news (R. Erber, Wegner, & Therriault, 1996), purchasing gifts for themselves (Luomala & Laaksonen, 1997; Mick & Demoss, 1990), helping others (Bagozzi & Moore, 1994; Cialdini, Darby, & Vincent, 1973), taking greater risks for greater rewards (Raghunathan & Pham, 1999), buying impulsively (Rook & Gardner, 1993), selling unwanted items (Lerner, Small, & Loewenstein, 2004), choosing the status-quo option (Luce, 1998), or simply procrastinating (Tice, Bratslavsky, & Baumeister, 2001).

Under the affect regulation umbrella, these examples all represent mood-lifting alternatives pursued in an attempt to restore or achieve the desired affective state (i.e., to close the gap between current and ideal affect). At the core of the dynamic affect principle is the implication that affect regulation is contingent on one's intuitive theories about the affective changing properties of the forward-looking cognitions and behavior. Thus, for affect regulation to fully operate, sad people must expect the behavioral activity to improve their current affective state. If that expectation is not present, the effect disappears. Several experiments have intrinsically or extrinsically controlled for the mood-changing properties associated with the behavioral activity. For example, helping is usually perceived as a mood-lifting opportunity because most people have learned the self-satisfying, and therefore uplifting, benefits associated with altruistic acts. This explains why, when experiencing negative affect, teenagers and adults are more willing to help compared to children who have yet to learn these associations (Cialdini & Kenrick, 1976). Food items, such as chocolate, have also been shown to present different mood-lifting expectations. Affect regulation via chocolate has a greater influence on women, who are more likely to perceive chocolate as a mood-lifting opportunity (Andrade, 2005; Grunberg & Straub, 1992). Similarly, sad participants are more willing to snack as long as they believe the action will regulate their affective states. Chronic tendencies such as general low expectations about affect regulation dampen many such effects (Tice, Bratslavsky, & Baumeister, 2001). Also, when people are led to believe their affective states are going to be temporarily frozen (i.e., the "mood-freezing pill" technique), attempts at upward affect regulation via aggression (Bushman, Baumeister, & Phillips, 2001) or helping (Manucia, Baumann, & Cialdini, 1984) also dissipate. Finally, specific emotions can alter the perceived mood-lifting opportunity of a given behavioral activity. As mentioned previously, anxious people take fewer risks than sad individuals (Raghunathan & Pham, 1999). Since anxiety stems from feelings of uncertainty, a risky choice may not represent an effective mood-lifting opportunity. Also, disgust has been shown to increase people's willingness to sell (Lerner, Small, & Loewenstein, 2004) probably because they have learned that "getting rid of" something when experiencing disgust will make them feel better.

Attempts at upward affect regulation can also be mitigated by competing goals. The principle of *conditional hedonism* implies that goals other than feeling better may lead individuals to give up a short-term pleasant opportunity (Erber, Wegner, & Therriault, 1996) or even to pursue an unpleasant path to achieve a competing goal, to improve performance, for example. Cohen and Andrade (2004) found that when people were expecting a task that required control over impulse buying, participants experiencing either positive or negative affect preferred to listen to mood incongruent songs in an attempt to neutralize stronger affective states prior to the task.

Positive affect and affect regulation

There is also evidence suggesting that people experiencing positive affect can, under certain circumstances, be less willing to take risks (Arkes, Herren, & Isen, 1988; Isen & Geva, 1987), to help

others (Forest, Clark, Mills, & Isen, 1979; Isen & Simmonds, 1978), or to seek variety (Kahn & Isen, 1993). Isen and Simmonds (1978) found that when the helping scenario displayed situational cues that threatened participants' current positive feelings, participants were less willing to help compared to a control (neutral affect) condition. Similarly, Kahn and Isen (1993) showed that the increase in variety-seeking behavior for happy subjects disappeared as soon as a product's negative features were included or made salient in the search context. In other words, as mood-threatening cues become salient, happy subjects—who have more to lose—anticipate negative affect, which triggers a strong self-protective regulatory mechanism.

Mood-threatening stimuli may also be more persuasive when the message attempts to convince people of the risks associated with a particular activity. Keller, Lipkus, and Rimer (2003) showed that a loss-framed (vs. gain-framed) message was more persuasive when people were experiencing positive affect, *increasing* the perceived risk associated with breast cancer as well as the participant's intentions to get a mammogram. In other words, as the consequences seemed more threatening, the message became more influential. The opposite was true for those experiencing negative affect, where the gain-framed message was more persuasive, probably as a result of its mood-lifting cues.

It has also been suggested that people may be more willing to take actions that will help them to maintain the current affective state. So, people would not only avoid what is bad in order to protect their current positive state but also approach what is good in order to maintain it (Clark & Isen, 1982). However, claims about mood maintenance effects must rule out people's willingness to act as a result of a more positive assessment of the environment (affect-as-information and/or mood congruency effects) rather than a deliberate attempt to "fuel" current positive feelings. Moreover, there is evidence inconsistent with the "mood fueling" proposition. First, whereas negative affect increases helping among adults but not among children (Cialdini & Kenrick, 1976), positive affect increases helping across both groups (Barden, Garber, Duncan, & Masters, 1981; Rosenhan, Underwood, & Moore, 1974). If children are less likely to perceive helping as a mood-lifting alternative, why would they be more willing to help? Similarly, Manucia, Baumann, and Cialdini (1984) showed that positive and negative mood increased helping. However, after a mood-freezing pill was administered, the effect of mood on helping disappeared in the sad mood condition *only*. Finally, Andrade (2005) showed that positive affect increased intentions toward chocolate tasting even among those who reported not perceiving chocolate as a mood-lifting alternative—in that case, most of the male participants. However, intentions toward tasting the product decreased for those in a bad mood who did not perceive chocolate as mood-lifting.

In short, when it comes to the impact of positive affect on behavior via affect regulation, it is important to make salient two distinguishable propositions. First, there are the *mood protection effects*, in which positive affect makes people more sensitive to mood-threatening cues, and less likely to take risks, help, or seek variety in order to preserve a current state (Andrade, 2005; Arkes, Herren, & Isen, 1988; Forest, Clark, Mills, & Isen, 1979; Isen & Geva, 1987; Isen & Simmonds, 1978; Kahn & Isen, 1993). Second, there are potentially *mood fueling effects* in which positive affect makes people more sensitive to mood-lifting cues, and, as a result, more likely to act in order to fuel an otherwise decaying positive feeling. However, direct evidence to support the latter proposition is still scant. The "fueling"-like effects have usually been explained by evaluation (affect-as-information and/or mood-congruency) rather than regulation mechanisms (Andrade, 2005; Manucia, Baumann, & Cialdini, 1984). Future research should address circumstances in which mood fueling effects are likely, independently of evaluation biases.

Our review suggests that from the more basic (perceptual) to the highest (decision making) cognitive levels, affective states can shape responses. In many circumstances, affect regulation seems to represent an important mechanism driving the effects. Changes in the perceived mood-

altering consequences of the cognitive or behavioral activity, the quantity and quality of the competing goals, and the strength of the affective signals will influence the impact of affect regulation on attention, retrieval, processing style, judgments, and decision making. However, many issues deserve further exploration. As described above, the role of perceived appropriateness and correction skills are important research avenues. Also, the impact of affect in judgment and decision making cannot be well understood without placing it in a more multifaceted context. For example, people could be led to discount or heighten the relevance of affect for a decision (in relation to other informational inputs or goals). So, a person with an eating disorder may be led to realize that s/he is eating too much, not because of hunger or even especially good-tasting food, but because of a mood repair need. One could, however, speculate that certain types of advertising for fattening food might engage mood repair needs. In that case, focusing on feelings may foster consumption.

We know relatively little about how affect regulation interacts with the other mechanisms (e.g., affect-as-information/mood congruency) also known to mediate the impact of affect on information processing and decision making. Direct evidence of the interaction of these mechanisms on both sides of the affective spectrum is still scant (Andrade, 2005; Manucia, Baumann, & Cialdini, 1984). Based on evidence from three largely unrelated research streams (helping, risk-taking, and eating), Andrade and Cohen (2007a) showed how a merger of the *affective evaluation* (affect-as-information and/or mood-congruency) and the *affect regulation* mechanisms can be critical to a more complete understanding of the affect-behavior relationship.

CONCLUSION

In the past 15 years, consumer research as a field has greatly matured in its understanding of the important role of affect in consumer behavior. The field has moved away from its original emphasis on mood states as “just another” source of contextual influence on consumer behavior and ad-induced feelings as “just another” determinant of brand attitudes. The field has moved toward a richer analysis of the very central role that affect—in its different forms: integral, incidental, task-related—plays in consumers’ experiences, decisions, motives, and actions. Yet, while our understanding of the role of affect in consumer behavior may be growing rapidly, the subject is barely in its adolescence. As illustrated by this review, so many important questions remained to be answered. For example, an important avenue for future research would be to analyze to what extent emotional experiences have lasting influences on consumer judgment, decision, and behavior— influences that persevere after the feeling state has dissipated. Some preliminary evidence suggests certain cascading mechanisms contribute to such lasting influences (Andrade & Ariely, 2007). It has also been noted that feelings seem to be interpreted differently depending on the questions that people are asking themselves when inspecting their feelings (Pham, 2004). These questions seem to function as lenses through which feelings are read and understood. Another important research avenue would be to better understand the types of questions that feelings are meant to answer. Our purpose in writing this chapter is to stimulate readers to tackle these and many other important issues we have surveyed, so that even greater progress can be seen when the chapter’s successor is written.

NOTES

1. As will be discussed later, more recent research suggests that incidental mood states may be more differentiated and have greater content specificity than previously thought (e.g., Lerner & Keltner, 2000, , 2001; Raghunathan & Pham, 1999; Tiedens & Linton, 2001).

2. The distinction between integral and incidental affect was first introduced by Bodenhausen (1993). We elaborate on this distinction by identifying a third type of judgment and decision-relevant affect: task affect.
3. This anticipatory use of the “how-do-I feel-about-it?” heuristic should be distinguished from the notion of anticipated or expected affect to be discussed further below. When relying on this heuristic anticipatorily, consumers appear to experience genuine momentary affective responses at the time of the decision (see Pham, 1998, Experiment 3). These momentary affective responses, which can be called *anticipatory* affective responses, are not merely affective beliefs unlike typical anticipated or expected affect.
4. These spontaneous thoughts should not be confused with the thoughts elicited by explicit requests to analyze reasons in judgments and decisions. As Wilson and his colleagues have repeatedly demonstrated, explicit requests to analyze reasons in judgments and decisions often trigger thoughts and reasons that are unrelated to the ones that people would otherwise generate and rely on spontaneously (e.g., Wilson, Dunn, Kraft, & Lisle, 1989; Wilson & Schooler, 1991).
5. Another explanation could be that chronic emotional states have lesser effects on risk-taking than momentary states.

Self-Regulation

Goals, Consumption, and Choices

KATHLEEN D. VOHS

University of Minnesota

ROY F. BAUMEISTER AND DIANNE M. TICE

Florida State University

Modern, economic society depends on consumers and their consumption, and, in some ways, the more they consume, the more successful the economy. But few consumers can really have all they might want. They have to curb their appetites to live within their financial means (or, if not within the limits of how much money they have, at least within the limits of how much they can borrow). They must restrain their consumption of some goods (such as cigarettes, fattening foods, and alcohol) that are bad for their health if consumed to excess. They have to restrain their consumption of goods (such as violent video games or pornography) that they perceive as a moral threat. They must restrain their consumption of goods (such as illegal drugs) that are illegal.

In short, the consumer's life is one of restrained consumption. In this chapter, our focus is on those restraints. Self-regulation is the inner psychological process by which people alter their responses to bring them into line with various rules and standards. In this way, it is also the crucial mechanism by which people curb their impulses to consume and keep their consumption within acceptable limits and parameters.

Overviews of the nature of consumer behavior note that setting goals and engaging in actions to attain them are the cornerstone of purposive consumer behavior (Bagozzi & Dholakia, 1999). For instance, investment and savings goals direct consumer spending (e.g., Shefrin & Thaler, 1988) and health goals, such as dieting, lead people to make different choices about caloric intake (Bagozzi & Edwards, 2000).

In this chapter, we detail how the study of self-regulation can explain and predict consumer behavior. Starting with the observation that self-regulation is needed when people deviate or want to deviate from rationality, next we will detail self-regulatory theory by specifying three ingredients of (a) standards, (b) the operation of moving oneself from current to desired state, and (c) monitoring one's progress along the way. Then we move from the basics to applications to consumer matters. Issues closely relevant to consumer behavior that have been linked to self-regulation are: impulsive and compulsive spending, vulnerability to persuasion, the effects of making choices on regulatory behavior, and self-regulation's role in making good decisions. Please note at the outset that this overview of research on self-regulation will focus only on conscious self-regulation; we do

not discuss the increasingly important effects of nonconscious regulatory processes on consumption. This chapter thus provides an understanding of the crucial role of self-regulation in consumer behavior. The relevance of self-regulation lies at the heart of marketing by understanding consumption in order to increase consumer welfare.

DEFINITIONAL ISSUES

Self-regulation can be understood as the process by which one response is overridden, allowing for a different response to take its place. To regulate something is to bring it under the control of rules or laws, and in the process to change it, and so self-regulation is a matter of bringing one's own behavior into line with standards such as laws, goals, morals, ideals, or rules. Essentially, the person's initial impulse may be to act, feel, or think in a particular way that goes against these personal or social standards, and so self-regulation enables the person to resist that impulse so as to respond in a more appropriate or desirable manner.

Self-regulation is most commonly seen in the struggle between impulses and restraints (cf. Hoch & Loewenstein, 1991). Oftentimes, a person will have a goal that requires inhibiting one response and perhaps replacing it with another. Situations that require self-control are those in which an urge that goes against the person's overarching goal is stimulated and therefore restraints to change, modify, or otherwise alter the impulse are required.

We use the terms "self-regulation" and "self-control" interchangeably, although other authors may use them to refer to different constructs. The main distinction that is sometimes made is to equate self-control with conscious, effortful processes, whereas self-regulation is a broader term that also encompasses nonconscious regulating processes such as how the body maintains a constant temperature or heartbeat. Our focus in this chapter will be exclusively on the conscious, effortful processes by which the self exerts control over its responses, and hence any distinction between conscious self-control and nonconscious self-regulation is irrelevant to this discussion.

The word "self" in self-control refers both to the fact that it is the self (the "I") that is doing the operating and that the self is what is being operated upon (the "me"). Impulses and urges are two terms also used interchangeably and they refer to a state that arises typically from the interaction between an underlying motivation (e.g., to increase good feelings) and a stimulus in the environment (e.g., a shiny piece of jewelry that is available for purchase). There are four broad domains in which self-control can be exercised (Vohs & Baumeister, 2004a). Mental control encompasses regulating cognitive processes, ranging from controlling attention (e.g., trying to concentrate) to suppressing unwanted thoughts (e.g., Wegner, 1994) and even guiding one's reasoning process toward a desired conclusion (Baumeister & Newman, 1994). Emotion control is essentially the effort to induce, suppress, or prolong an emotional state. Impulse control typically involves keeping oneself from acting on desires or appetites deemed unsuitable, whether these be food cravings, addictive yearnings, sexual or violent inclinations, or other temptations. Last, performance management encompasses the attempt to perform at a certain (usually high) level, such as persistence in the face of failure or fatigue, speed/accuracy tradeoffs, or trying not to choke under pressure.

We start with an example that illustrates the ingredients of self-regulation. A young man wants to buy a pickup truck but cannot afford it. He assesses how much money he has and how much money he needs to buy the truck, which indicates how much more money he needs to have. Accordingly, he forms a plan to save some money from his weekly paycheck, which will enable him to afford the truck in time for, say, a planned camping trip next summer. Along the way, however, he may have to resist temptations to spend his income on a new stereo system. His success depends on monitoring his progress at saving money while also resisting these intervening temptations.

The example of saving up to buy includes the four main ingredients of self-regulation. First, one has to have a goal, in this case to save enough money to buy the truck. Second, one has to be motivated to reach the goal: the more he wants the truck, the more likely he is to be willing to make the efforts and sacrifices required to save. Third, he has to monitor progress toward the goal, rather than just vaguely stuffing a few bucks into various envelopes scattered in his desk and sock drawer now and then. (In particular, he has to keep track of how much he has saved and how much he needs, plus ideally whether he is on schedule of saving enough to get the truck in time for the camping trip.) Last, he will need the willpower to resist other temptations in order to keep saving toward his goal.

STANDARDS

Standards are the ideals, norms, goals, or other rules or guidelines that provide the endpoint of the regulatory chain. Akin to the idea that the first step in the buyer's decision process involves consumers recognizing that they have an unmet need, self-regulators' first step is to recognize that there exists a standard that they want to meet. Typically, this step is accompanied by an almost-immediate comparison to see where one is located with respect to the standard. (We return to the idea of monitoring in a subsequent section.) Assuming there exists a difference between current and goal states, the person needs self-control. If there is no discrepancy, there is no need for self-control. Much of the strain on self-regulation can sometimes be alleviated by modifying standards. For example, whereas many people struggle to lose weight so as to conform to social standards of fashionable thinness, some instead join the so-called size-acceptance movements that essentially say it is okay to be fat. In the same vein, recent decades have witnessed a marked reduction in the social stigma associated with bankruptcy and with out-of-wedlock reproduction, thereby reducing the demand on people to regulate their behavior as tightly as they may have in past decades to avoid those outcomes.

The more specific the standard, the better able people are to reach the goal. Specificity in setting the goal helps at two levels. One, being specific about the goal reduces the goal's abstractness, which clarifies the steps needed to reach the goal (see Gollwitzer, 1999; Gollwitzer & Brandstätter, 1997). Instead of trying to reach the abstract goal to "save money," the consumer who sets the more concrete goal of "forgoing a latte three times a week" is better positioned to reach the ultimate goal of saving more money.

Two, specific goals (or the creation of subgoals) allow for better monitoring of progression toward the goal. With a precise endpoint, one can see how to measure current states and distance to the goal. Grocery shopping with a list makes it easy to see which foods still need to be acquired by looking at which foods are already in the cart. In addition to having a specified goal, having only one goal makes self-regulation more successful than when people have two or more conflicting goals. Research on children similarly shows that when adults give different and inconsistent rules to children, the children behave inconsistently (Maphet & Miller, 1982).

In general, having clear standards is a benefit to goal attainment, but new research suggests that holding highly rigid standards can at times lead to worse self-regulation. Research by Soman and Cheema (2004) found that when people violated a standard they had set for themselves, their subsequent goal-directed behavior faltered—with the result being even worse than the performance of people who held no performance standards. The researchers found that a feeling of failure from the violation of standards was key, especially when goals were perceived as being "all of none." This deleterious outcome is best avoided by choosing moderate standards: Standards that are too low may not motivate people, but those that are too high may demotivate people via the potential for

perceptions of standard violations and concomitant feelings of failure. Baumeister, Heatherton, and Tice (1994) compared the stringent, so-called “zero tolerance” standards to a military tactic of putting all one’s troops on the front line. It offers the best chance of preventing any breach, but it leaves nothing in reserve to cope when a breach does occur. They suggested, for example, that the zero tolerance approaches help explain the seeming paradox that the United States has relatively high rates of both teetotalers and alcoholics, in contrast to other cultures that emphasize controlled drinking as the standard.

One motivational theory that has had widespread success in predicting consumer behavior centers on differences in behavioral guides. *Promotion* behavior pursues positive outcomes, whereas *prevention* behavior avoids negative outcomes (Higgins, 1997). Promotion behavior is aimed at achieving ideal standards, such as hopes, wishes, and dreams. Prevention behavior is geared toward goals that people feel obligated to achieve, such as duties and responsibilities. Research has shown that when people are in a promotion mode and geared toward goal attainment, their actions are best described as eager, whereas when people are in a prevention mode, vigilance is the best descriptor of behavior.

Moreover, if a situation calls for a strategy that contrasts with the type of goal being pursued (e.g., a promotion goal that is pursued by being vigilant), people fail to achieve their goals more often than when goal types and behavioral strategies are matched. Recent research suggests that promotion and prevention may not only be suited for certain strategies, but for information processing routes as well. Research by Pham and Avnet (2004) revealed that ideal standards bias people’s reactions in terms of the emotions evoked by incoming information, whereas ought standards lead to processing a message based on its content. That different standards activate different psychological systems (affect vs. cognition) has broad implications for behavioral change strategies. This finding, in addition to providing information such as knowing whether a woman seeks to lose weight because of her dreams of fitting into a shapely swimsuit or because her partner told her to do so, will help predict whether her diet will be upset by a distressing incident versus new findings indicating that weight is more genetic than people once thought (i.e., emotional vs. cognitive information-processing styles).

One type of goal conflict occurs when people come up against a seemingly unattainable goal. Outside the laboratory, it is often difficult to know whether one’s goals are unattainable or unrealistic. A lack of progress toward the goal may be the first sign, but such signs are hard to read. For example, consider the thousands upon thousands of young men who sacrifice years of their lives, plus their best educational opportunities, plus their physical well-being in pursuing the goal of becoming a professional athlete. The immense rewards associated with such success make the dream appealing, and the young men can see exemplars who have achieved that level of success on television any time. But far more than 99% of those who pursue the dream will fail, and it may take a very long time (often until one has spent 5 years in college, with no degree) to realize that one is never going to succeed at that level.

Wrosch et al. (2003) showed that people who disengage from seemingly impossible goals are mentally healthier than those who stay entrapped in the pursuit of this type of goals. In this case, the goal of using one’s limited effort and time effectively conflicts with trying to achieve the impossible, and the healthiest strategy is to drop the frustrating goal. Although little is known about when people consciously decide to abandon a goal (cf. Shah, Bodmann, & Hall, 2005), this line of research has much theoretical and practical importance.

Another type of goal conflict is probably endemic to consumer behavior, because almost all consumers face a variety of tradeoffs in which they want incompatible things. Most fundamentally, perhaps, consumers want to save their money but also to acquire goods and services. And even if

they are determined to purchase, there are endless further tradeoffs: higher quality versus lower price; sensible comfort versus fashionable looks; name brand reputation versus more immediate availability; higher safety rating versus better gas mileage; less filling or great taste. Rational choice is supposedly the human cognitive tool for making such choices, but recent evidence suggests that requires effort and consumes some of the same resources required for self-regulation, as we will explain shortly.

MOTIVATION AND COMMITMENT; OR, THE “GUN TO THE HEAD” TEST

Having standards does not mean that good self-regulation will necessarily follow. Recall that people may have standards but perceive that their behavior already meets these standards. Others may see that they fall short of standards but not care. People must be motivated to enact a behavioral change. The motivation to self-regulate is probably crucial to its success, although it is probably the least studied of the four basic ingredients.

How common are irresistible impulses? Some people claim—and some legal institutions condone—that under some circumstances, impulsive actions may not be controllable due to either strong emotional states or other internal breakdowns of will. Self-regulatory researchers generally find these claims dubious. Suppose, for example, that a compulsive gambler was truly unable to resist the temptation to gamble. Taken to an extreme, this would mean that if a gun was held to the head of the person who was about to lay down another bet at the blackjack table, he or she could not help but place that bet. Yet, this rarely (if ever) happens: People, if they really want, are able to avoid giving into all kinds of impulses (Baumeister & Heatherton, 1996). One of the FBI’s foremost experts on serial killers observed that although the killers sometimes claimed that their homicidal impulses were irresistible, not one of the thousands of murderers documented by this group had been committed in the presence of a police or security officer (Douglas, 1996). Apparently, the irresistible impulses could be resisted if the chances of getting caught right away were high.

Considering the truly irresistible impulses is a good way to appreciate the contrast. A person cannot remain standing forever, and sooner or later will sit, lie, or fall down, even if threatened at gunpoint to remain standing or else. People cannot hold their breaths indefinitely, and even if the willpower is sufficient to keep them from breathing for a long time, they will pass out and start breathing. They cannot remain awake indefinitely, and some people die because of falling asleep on sentry duty or while driving. There are of course a few other bodily functions that are likewise truly irresistible, and it is appropriate to refrain from blaming people who break down under such circumstances. In contrast, the spouse who ruins the family’s monthly budget by spending an inordinate amount on a new jacket, and who seeks to justify the act by saying “I couldn’t resist,” is almost certainly speaking merely figuratively (which is to say lying).

For consumer behavior, the important implication is that purchasing impulses are in fact almost always resistible. But consumers may prefer to conceal that fact from themselves and their families. “I had to have it, I couldn’t help myself” is much preferred over the more realistic “I deliberately chose to blow a lot of our money on selfish gratification for myself.”

People may get the motivation to control themselves from the situation; the crime examples illustrate the power of external punishments. Or rewards may drive the motivation to control oneself. Some empirical work has found that even when the ability to engage in self-regulation is significantly impaired, people can nevertheless control themselves when an incentive is offered, such as money or believing that one’s self-control efforts will be a benefit to oneself or a vulnerable group (Alzheimer’s patients) (Muraven & Slessareva, 2003).

The outcome of the self-control endeavor may be a sufficient enough prize to encourage controlling oneself. A model of self-regulation from the health domain (Rothman, 2000) describes the desire to initiate a behavioral change as stemming from the positivity of the outcome. Thus, most people believe that smoking cigarettes is bad for them, and many have quit smoking in order to improve their odds of avoiding lung cancer in later life, but others may not value that outcome. Teenagers who disdain old-age health issues as absurdly remote, soldiers in combat zones who doubt their chances of surviving the war, prisoners serving life sentences, and AIDS sufferers, among others, may not find the increased chance of escaping lung cancer in the distant future a sufficient reason to give up the pleasure of smoking.

Motivation may come from perceptions of the difficulty (or possibility) that the goal can be attained. One model that focuses on outcomes derived from consumption (Bagozzi & Dholakia 1999) places self-efficacy at center stage, such that people's beliefs about the skills they possess to achieve their goals is crucial to their willingness to self-regulate. This model emphasizes self-efficacy as key to whether and how the consumer will approach the self-control task. Self-efficacy is particularly related to the means chosen to reach the goal. Thus, if a person considering a diet thinks, "If I am offered cake at parties, I am confident that I can refuse and instead I eat fruit," he or she is displaying self-efficacy and its aid in selecting suitable means to attain the larger goal of limiting caloric intake.

Research on the overconsumption of food (binge eating) supports the importance of self-beliefs in motivating people to self-regulate—as well as the demotivating effects of not believing in oneself. This research shows that women who hold high standards for thinness but believe that they are overweight have high binge eating tendencies—but only if they also doubt their ability to reach their goal (Vohs et al., 1999, 2001). Women who believe that they close the gap between their current (perceived) body image and their desired body image do not overeat.

Last, motivation may also depend on beliefs about how self-control works. Recent work suggests that laypersons have personal beliefs about how self-control operates (Mukhopadhyay & Johar, 2005). Moreover, personal theories about self-control can help predict variance in goal attainment, presumably because they influence commitment to self-regulatory goals and subsequent motivation.

MONITORING AND FEEDBACK LOOPS

Monitoring involves being aware of the self's behavior or responses and comparing them to a standard. Breakdowns in the monitoring aspect of self-regulation are not as well understood as are breakdowns in the other ingredients, but nevertheless breakdowns in monitoring are a key reason that goals are not met. Monitoring is perhaps more central to understanding consumption than other aspects of goal attainment, which suggests that more work could be done to underscore its value in consumer behavior.

The study of monitoring is also worth pursuing for practical reasons. Baumeister et al. (1994) proposed that monitoring is the aspect of self-regulation that is most readily susceptible to improvement, and so whenever one desires to improve self-control, improving monitoring generally offers the most promising opportunity for substantial (and immediate) improvement. Thus, if someone has money problems, it may be difficult to increase income or willpower, and revising standards downward (to accept being on the verge of bankruptcy) may be problematic. Nonetheless, keeping close tabs on one's income and expenses, such as by keeping a daily written record of spending, is often both viable and effective. Likewise, it is no accident that successful dieters count calories and otherwise carefully monitor what they eat, and that the cessation of monitoring often undermines dietary efforts.

One reason (and there are many) for the difficulty of self-control is that effective self-control necessitates that people monitor their behavior, but the act of monitoring means a focus on the present time (Vohs & Schmeichel, 2003). This “extended-now” state renders people vulnerable to incoming urges and impulses and makes long-term goals seem less pressing. This extended-now theory of self-regulation is supported by studies showing that self-regulation changes time perception, such that self-regulators feel that time is moving more slowly as compared to non-regulators (and as compared to veridical durations). Monitoring one’s progress, although being an integral part of goal strivings, may, unfortunately, bring about perceptions that time is moving slowly, which in turn reduces self-regulatory efforts (Vohs & Schmeichel, 2003).

Classic work on chronic dieters demonstrates that not only the reliability or strength of the signal is important in monitoring, but also the interpretation of the feedback. Research on dieting versus nondieting¹ shoppers shows that dieters buy less when they have not recently eaten than when they have recently eaten, whereas the opposite pattern holds with nondieters (Nisbett & Kanouse, 1969). Why would dieters buy less when they are hungrier? The idea is that the bodily signals that one has not eaten in a while is a positive, reinforcing signal that the goal of limiting caloric intake is being met. Therefore, dieters—who have the goal of restricting caloric intake—buy less food when they get feedback that they are meeting their dieting goals.

As another example of how interpretation can undermine monitoring, Gilovich (1983) addressed the seeming paradox that many gamblers continue to gamble and even seem to remain optimistic, even though most lose more than they win, and, in fact, long-term net losses are almost guaranteed by the structure of the gambling system (by which, for example, the casino or indeed the state government must make a net profit, so it pays out less in winnings than it takes in). Accurate monitoring would have to reveal to gamblers that they had lost more often than won. But Gilovich (1990) found that gamblers discounted some losses as “near wins” and so felt encouraged despite losing. They were much less likely to discount their wins as “near losses.” By taking credit for all successes and discounting some wins, they were able to transform the objective feedback of overall loss into the subjective impression of efficacy and confidence at “continued” success.

Monitoring allows people to assess distance to the goal. This can be done by looking back at how far one has come or how much more has to be done. A new study suggests that seeing how far one has come may be more effective in promoting self-regulation than how much more work is ahead. Nunes and Dreze (in press) gave loyalty cards to customers at a professional car wash. Some customers were given a card that required 10 car wash purchases before one free car wash was earned, whereas others were given a loyalty card that required 8 car wash purchases before the reward. However, those in the 10 car wash condition were given their card with two “free” stamps already affixed to it, making the amount of effort needed to reach the goal equivalent. Perceptions of progress mattered, though—34% of customers filled their card and earned a free car wash in the 10 washes-but-2-free condition, whereas only 19% did in the 8 washes condition. Moreover, the goal gradient was steeper for those in the 10-but-2 condition, such that after receiving the loyalty card, they came to the car wash more often than did the 8 wash condition customers. Believing that one has come a long way apparently increases commitment to the goal, thereby leading to heightened efforts to reach it.

OPERATIONS: USING SELF-REGULATORY STRENGTH TO MOVE ONESELF TO THE GOAL

Even if a consumer has clear, unconflicting, and appropriate standards and monitors his or her behaviors, the goal will not necessarily be met. Without the capacity to move oneself from current to goal state, the best laid plans and all the monitoring in the world will not be good enough. The

strength model of self-control has been the most comprehensive model in terms of specifying what allows people to move toward a goal. Self-regulation, from this perspective, is governed by a finite supply of energy that is used in all controlled responses and actions (Baumeister & Heatherton, 1996; Baumeister et al., 1994; Vohs & Baumeister, 2004b).

The strength model depicts the ability to get oneself to the goal as a function of the amount of self-regulatory resources available when exhibiting the response. Because self-regulatory resources are put toward all acts of self-control, the supply is rather fragile and precious and, according to the model, can diminish to a point where impaired self-control can be observed. Therefore, laboratory experiments testing the strength model of self-control typically have used a two-task paradigm. The first task varies on its self-control demands such that some participants are given a task that is thought to require expending self-regulatory resources, whereas others are given a neutral task that does not require self-regulatory resources. The second task, then, is the measure of self-control ability. To test the strength model, the hypothesis put forth is that differences in the second task reveal that the experimental condition in the first task was indeed an act of self-control that presumably depleted the self's resources. Indeed, the work of over 30 published experiments (e.g., Baumeister et al., 1998; Muraven et al., 1998; Schmeichel, Vohs, & Baumeister, 2003; Vohs, Baumeister, & Ciarocco, 2005; Vohs & Heatherton, 2000) supports the idea that the "operate" component of self-regulation can be modeled as a stock of energy that becomes temporarily reduced with use, with the consequence being disrupted self-control. Several extensions of the model that are particularly applicable to understanding consumer behavior are discussed hereafter.

Early investigations of the model focused on confirming basic tenets. Here, researchers took core self-control tasks, such as persisting at a different task, controlling one's emotions or suppressing thoughts and tested whether engaging in these activities left people with less ability to engage in another self-control act. For instance, Baumeister et al. (1998) asked participants to control either emotions to an emotional film, or to watch the film naturally (without instructions). Subsequently, they were given a set of difficult anagrams to solve. In line with expectations from the strength model, participants who had to modify their emotions solved fewer anagrams. Notably, both a happy and sad film were used and type of film did not affect anagram performance; only being in a condition that required emotional modification mattered.

Manipulations of thought suppression complemented these findings. One experiment, which asked participants to suppress thoughts of a white bear (Wegner, Schneider, Carter, & White, 1987) versus complete simple mathematical problems, showed that the former group was less able to control their emotions later when asked to do so (Muraven et al., 1998; Study 3). A host of similar studies confirmed the basic tenets of the model using a variety of different manipulations and dependent measures. Therefore, we have concluded that self-regulation relies on a precious, but finite, resource that is taxed when self-control is needed. The term "regulatory resource depletion" is now used to suggest phenomena when one does not have the strength to exert proper control over one's actions.

An important extension of the regulatory resource model indicates that the same resource is used for making choices. A series of studies by Vohs, Baumeister, Twenge, Schmeichel, and Tice (2005/under review) showed that after people make a series of choices, their self-control falters and fails just as it does following prior exertions of self-control (see also Baumeister et al., 1998). In particular, participants in several studies were asked to make a series of binary choices between various consumer items (e.g., would you rather have a red or a blue t-shirt? Would you rather have a vanilla scented candle or an almond scented candle?). Others simply rated the same items on various dimensions, including whether they had used them in the past 6 months. Those who made choices were subsequently poorer at self-control on a variety of measures, including holding one's hand in ice water or making oneself consume a healthy but bad-tasting beverage.

Because the same resource appears to be used for both decision making and for self-regulation, Baumeister et al. (1998) introduced the term “ego depletion” to refer to the state of diminished resources. The term “ego” was adopted in a deliberate homage to Freud, who was one of the only psychologists to speak (albeit rather vaguely) of the self as an energy system.

For consumer psychology, the implication is that two perennially central issues in consumer behavior—namely decision making and self-control—rely on a common resource that becomes depleted when one engages in either activity. Hence either activity can have an adverse effect on the other. Making effortful decisions is likely to impair subsequent self-control, and, conversely, exertions of self-control may reduce the care and effort that people put into their subsequent choices. Examples of both patterns will be covered below.

APPLYING THE STRENGTH MODEL TO CONSUMER ISSUES

Overeating

Eating is one of the most fundamental consumption acts. People must eat to survive, and yet society, dietary, and health reasons prompt many people to regulate their caloric intake at some point in their lives. However, the outlook for people wanting to lose weight and maintain their slimmer size is dim: comprehensive long-term research (Kramer, Jeffery, Forster, & Snell, 1989) revealed that fewer than 3% of all dieters will manage to keep the weight off, and, by 5 years after their weight loss, most will weigh more than they did when they began dieting.

Thus, the concept of limiting food intake is a tantalizing topic for self-control theorizing because, unlike other consumption domains such as drinking alcohol, smoking cigarettes, or even having sex, people need to take in calories to live. Consequently, achieving the goal of losing weight by cutting caloric intake cannot be met using the same strategies as could be used to limit alcohol intake, namely refraining from consumption altogether.

Thus neither the advantages nor the inherent problems (see above) of zero tolerance self-regulation policies are relevant to eating, and controlled moderation is the only viable strategy for controlling food intake. Stopping oneself from taking in any calories is a route that no one can take without landing in the hospital, which therefore means that people wanting to control their food consumption must use other strategies. Consequently, the intricacies of dieting make it one of the most perplexing and difficult regulatory tasks that one may take on.

Being exposed to forbidden foods is a situation that many dieters face and if they intend to stick to their diet, they must override their desire to eat the tempting food. Baumeister et al. (1989) recruited a sample of hungry undergraduates (but who were not selected because they were dieters) and created a situation to mimic the forbidden-food situation that dieters often face. Participants were seated in front of a tray of chocolate chip cookies that had been freshly baked in the laboratory (with the aroma of warm chocolate wafting throughout the room for everyone to smell), chocolate candies, and a rather large bowl of radishes. Some participants were told they could eat as many of the cookies and candies as they wanted, whereas participants in the forbidden-food condition were told that their task was to eat the radishes. (There was also a no-food condition.) After 5 minutes of privacy with the foods, participants were given a geometric puzzle to solve, which was unsolvable, although, of course, they did not know this. Persistence in the face of frustration and disappointing failure is one standard measure of self-regulation, because the vexing failures presumably create the desire to quit so as to do something else instead, and, in order to persist, the performer must override this urge to quit. Participants in the forbidden-food condition were less persistent at the puzzle as compared to participants in either of the other two conditions. Being tempted by the chocolates but not being able to indulge presumably taxed the resources of those participants, which therefore impaired their ability to continue on the difficult cognitive task.

Another set of studies examined the effects of self-regulatory resource depletion in a context in which people have pre-established consumption goals. In these studies, chronic dieters were the main focus, and the hypothesis was that underlying differences in long-term goals render people differentially affected by the same situational self-control demands. Vohs and Heatherton (2000) asked dieters and nondieters to watch a boring video on Bighorn sheep while being seated either next to or far away from a tempting bowl of M&M candies. This formed the temptation factor, which was combined with instructions that the candies were available to be eaten (“go ahead, help yourself”) or that the candies were needed later in the day, and therefore “please don’t touch” them. After watching the boring video for 10 minutes, participants were moved to a different room to “taste and rate” three flavors of ice cream. Ice cream consumption was the measure of self-control.

Given that nondieters do not (by definition) control their caloric consumption, they would not have to override the temptation (and hence become depleted) to eat the yummy chocolates. (That said, it was not the case that the nondieters consumed many M&Ms—only five nondieters ate the snacks and even they did so minimally.) Hence, nondieters’ ice cream intake was predicted to be relatively unaffected by the two factors of temptation and allowance to eat the snacks. For dieters, however, the urge to eat the chocolates must be acted on. Therefore, Vohs and Heatherton expected that only dieters would expend regulatory resources in the presence of tempting snacks. However, if an external force prevented them from having to exert *self*-control to not eat the candies—such as a caution from the experimenter to not partake in the snacks—then their supply of self-regulatory resources would be spared. As a result, the researchers predicted that ice cream consumption would be highest among dieters who sat close to the snacks and were allowed to eat them.

The predictions were confirmed. Dieters ate significantly more when they were highly tempted by sitting next to the M&M candies and were told the candies were available to be eaten. Notably, however, dieters ate the least when they were seated far from the chocolates and were told they could indulge in them (which, being dieters, they did not). This pattern may represent an inoculation effect, which would be an intriguing idea for future depletion research. And as expected, nondieters’ ice cream eating was not determined by whether they had sat near or far from the M&Ms nor whether they were allowed to eat the candies.

A second study replicated the loss of self-control among dieters after having engaged in emotion regulation (Vohs & Heatherton, 2000). In this experiment, dieters watched a sad movie about a woman on her deathbed saying good-bye to her husband, two sons, and mother. Participants were asked either to suppress their emotions or to watch the movie naturally. Ice cream eating again represented self-regulatory ability. As expected, asking these women to engage in emotion regulation, as opposed to being able to watch the same movie but without having to suppress sad feelings, led them to eat more ice cream later. Both groups reported similarly negative feelings after the movie, meaning that differences in mood did not account for eating differences, but having to stifle those feelings led to a depletion of the resource that later would have helped them control their ice cream consumption.

A third study showed that persistence drops after dieters have had to overcome the temptation of forbidden foods. In this study, being highly tempted by an array of snack foods led subsequent persistence on an embedded-figures task to be impaired, relative to persistence among dieters who watch the same boring film and looked at the same snack foods but who did so from across the room.

Thus, regulating the consumption of food determines and is determined by the availability of self-regulatory resources—but only among people for whom caloric regimens were highly important and thus demanded much regulation. Moreover, having to defeat the desire to eat a tempting, but forbidden, food in order to make oneself eat a less appealing, but healthier, food also takes away from the capacity to later bring one’s performance in line with standards.

Overspending: Impulsive Purchases

Just as controlling one's eating represents a special kind of self-control problem, so does spending. If one includes the paid consumption of energy and utilities such as water, the typical modern citizen spends money every day. Much spending is fairly inevitable, and other spending is appropriate and judicious. Still, some money is spent impulsively and in ways that the consumer may later regret. Vohs and Faber (2005) turned to the self-regulatory resource model to help explain why people spend money impulsively.

Impulsive buying is defined purchases that result from an urge that arises spontaneously within the consumer to buy. In impulsive purchasing, the desire to purchase is unreflective (Strack, Werth, & Deutsch, in press) and not based on any careful considerations of why the product should be acquired (Rook & Fisher 1995). Vohs and Faber surmised that impulses to buy would arise and be acted upon more often when people's self-regulatory capacity is reduced than when it is fully intact. The results of empirical work support this idea.

Two studies manipulated attentional control demands as a way to alter self-regulatory ability. Participants watched an audioless video of a woman being interviewed that, at the same time, showed irrelevant words appearing at the bottom of the screen every 30 seconds. Some participants were not told anything about the irrelevant words, whereas those in the depletion condition were told not to look at the words and if they found themselves orienting toward the words to revert their eyes back to the interviewee. In one study, participants were then given a scale to measure immediate buying impulses; in another study, participants were shown high-end products (e.g., watches, appliances) and asked to state the price at which they would be willing to purchase the item. Both studies showed an effect of self-regulatory resource availability on impulsive spending tendencies: participants who had earlier used their resources to orient their attention away from a distracting stimulus later reported stronger urges to spend impulsively (Study 1) and gave higher willingness-to-pay rates (Study 2), as compared to participants who did not engage in attention control. Feeling a spontaneous urge to buy is, as we saw earlier, the root of impulsive spending, and one way to control that urge is to believe a product is not worth its monetary price (Rook & Fisher, 1995). That self-regulatory resource depletion affected impulsive spending tendencies both at the level of the impulse and the cognitive strategies to rein in that impulse is noteworthy.

Moreover, this research found that actual impulsive spending was affected by resource availability. One of these studies asked participants in the resource depletion condition to suppress thoughts of a white bear; the other study asked participants to read aloud a boring text with emotion. Subsequently, participants were given the opportunity to buy in a spontaneous, ad hoc purchasing situation in a mock store. As predicted, participants whose resources had been depleted spent more impulsive than did participants who had not expended their resources. This effect was found in terms of purchases of bookstore-like products, such as school insignia pens, coffee mugs, and decks of playing cards (Study 3) as well as grocery store items, such as cookies, pretzels, and potato chips (Study 4).

Moreover, the latter two studies incorporated the idea of underlying tendencies toward a certain type of self-control failure, in a similar manner as was done in the work on chronic dieters (Vohs & Heatherton, 2000). In this work, however, generalized tendencies to want to spend money impulsively were measured prior to the experimental manipulation of self-regulatory demands. Similar to the findings on dieters, Vohs and Faber (2005) also found that the effect of self-regulatory resource depletion was exacerbated among people who normally feel strong desires to buy impulsively. In contrast to the work on dieters versus nondieters, however, was the fact that even participants who were low in general impulsive spending tendencies showed heightened purchasing behavior when depleted. This effect is probably due to the idea that nondieters and nonimpulsive spenders differ in

that almost everyone needs to control their spending at some level, irrespective of whether buying impulsively is generally a problem, whereas nondieters are presumably not controlling their eating to the same extent.

Hence, spontaneous urges to buy something too are affected by self-regulatory resources (Vohs & Faber, 2005). Whether from regulating attention, stifling thoughts, or modifying one's behavior to appear unemotional, people who had engaged in self-control earlier were more likely to buy impulsively. Perhaps the most intriguing result of this line of research is that decreases in the self's controlled processes strengthen the feeling to buy impulsively. Theoretically, the strength of the urge and inhibitions on that urge have been considered to be orthogonal, but to detect a change in the potency of the impulse with depletion suggests that empirically the two core components of self-control may be intricately related. Research at the intersection of the urge and the self's regulatory resources (Vohs & Mead, in preparation) presents an exciting new avenue of study.

Thus far we have discussed about impulsive consumption in the context of purchasing. Impulses may also affect what people consume in another fashion, namely watching movies. The core idea behind this research (Novemsky & Baumeister, 2005) was that, at times, choosing a more virtuous option may require overriding an impulse to do something nonvirtuous, and so self-regulation is required for choosing the path of virtue. In one study, Novemsky and Baumeister (2005) offered students a choice of a movie to watch (for later, not immediate viewing). The options contained either intellectually edifying fare and low-brow sleaze. These options were presented either before or after an intensive study session, which was assumed to be somewhat depleting. Different levels of depletion were inferred based on study time in the library (i.e. by having students make the choice as they first approached the library to begin the evening's studying, or as they departed after several hours of work) or were experimentally manipulated by having participants make a brief series of choices and decisions (e.g., Vohs et al., 2005). Sure enough, when students were fresh and their resources were not depleted from studying, they exhibited a marked preference for the highbrow films. After a study session, however, they shifted heavily toward the lowbrow fare.

The implication is that some consumer decisions present a challenge between higher and lower impulses. Self-regulation enables human beings to override the latter sort of impulse in order to pursue the former. But when self-regulatory resources have been depleted, preferences shift toward the less virtuous product.

Making Intelligent Decisions

The ability to make the right decision should (by definition) free consumers from a great deal of regret. However, because the "right" option is not always readily apparent when one faces a decision, the human psyche has developed highly intelligent methods for determining the best answer, such as cost-benefit analyses. For instance, consumer theorists recognize that consumers' attempts to control consumption frequently entail assessing a decision's economic costs (Hoch & Loewenstein, 1991). As we have already said, both decision making and self-regulation are crucial aspects of the self's executive function, and both seem to consume the same resource (Baumeister, 1998). The agentic self must oversee the active parts of the decision making process, such as problem solving, but it is not involved in automatic information processing actions such as categorization. Indeed, one review of the problem solving literature (Crinella & Yu, 2000) concluded that almost all problem solving requires executive functioning. On that basis, Schmeichel, Vohs, and Baumeister (2003) proposed that the logical style of problem solving, with its inefficient manner but high-quality output, would be deeply related to self-regulatory resources. The fewer resources people have, they predicted, the worse they would be able to solve problems.

The first test of the hypothesis involved a standard attention control task in which participants' attentional abilities were challenged by having to ignore distracting words during a video they were to be watching or being allowed to gaze at the distractors as much as they wished (similar to the method described earlier). Next, participants solved problems from the analytical section of the Graduate Record Examination (GRE), an entrance exam required to apply to most graduate studies programs. The results showed clear support for the hypothesis, in that participants who had earlier controlled their attention completed fewer GRE problems, got fewer problems correct, and achieved a worse effort/speed trade off quotient overall as compared to participants whose earlier task did not involve self-control (Schmeichel et al., 2003).

Another experiment tested the idea that only higher-order, intelligent processing would be interrupted by self-regulatory resource depletion by including a task that required a rudimentary mental task as well one that needed more advanced thinking. In this study, the manipulation of self-regulatory resources was followed by the reading comprehension section of the GRE and a nonsense syllable task, which is used often in cognitive science as a working memory task (note that the tasks were counterbalanced in order). In the former task, participants read a passage about Toni Morrison's writings and her identity as a black, female author and, in the latter, participants were asked to read a list of 15 nonsense words and memorize them in the space of 60 seconds. As expected, self-regulatory resource depletion condition related to ability to correctly work out the answers to the reading comprehension questions but was unrelated to memorization skills.

Thus far we have presented evidence that depletion impairs intelligent thought. But does it actually alter decision making? A series of studies by Amir, Dhar, and Baumeister (2005/unpublished) had participants first undergo a brief depletion manipulation and then confront one of several standard decision problems. The results suggested that ego depletion brought on by brief acts of self-control can shift decision making toward simpler, lazier, and more superficial styles of decision making. Several such patterns were observed. First, depleted participants seem less inclined to face up to tradeoffs in a cognitively complex, integrative manner. Simonson (1989) proposed that choosing a compromise option requires more cognitive work than simply choosing an extreme one, because the compromise requires the person to process multiple, conflicting criteria and trade some degree of one for some measure of the other. Amir et al. (2005) found that depleted participants were more likely to choose extreme options over compromise ones, as compared to non-depleted participants.

Second, depleted participants showed a stronger version of the asymmetric dominance effect (also called the attraction effect; Huber, Payne, & Puto, 1982). This effect can be understood in the context of a decision problem that has both an easy and more difficult choice. That is, it is a choice between three options, two of which are quite different in specific attributes but similar in overall quality (hence the difficult choice), and the third is a decoy that is clearly inferior to one of the other options on all attributes (the easy choice). Depleted participants avoided the difficult choice by letting the easy decision stand in for the difficult one as well. In other words, depleted participants were more likely than others to pick the item that was superior to the decoy.

Third, depleted participants were more likely than others to choose to do nothing. In this pair of studies, participants were asked to choose between two products (e.g., two cell phones) but also had the option of taking neither and "going to another Web site." Whereas nondepleted participants would often make a selection from what was offered, depleted ones tended to avoid the choice.

The bottom line is that making decisions can be an effortful, thoughtful task in which the various product options and attributes are carefully weighed and compared—but this sort of decision process requires considerable resources. When people's resources have been depleted by prior acts

of self-control, people shift toward more simplistic and less effortful styles of choosing. They become more prone to biases, and they also become more prone to choose not to choose anything.

In short, consumers' ability to make good decisions depends on the extent to which they have previously engaged in self-control. When consumers inhibit impulses or force themselves to do what they do not want to do, they will be less prepared to make rational decisions, especially under circumstances of complex layers of information. Decision making, then, is more than a function of opportunity or willingness, this research implies, but also executive functioning ability.

DECISION MAKING MAKES CONSUMERS VULNERABLE TO A LOSS OF SELF-CONTROL

In the previous section, we examined rational decision making as an outcome of self-regulatory resource depletion. In the current section, we look at the opposite side of that equation, whether making choices affects subsequent self-control.

Recall that we described the relationship between decision making and self-regulation as related to their constituency as components of executive control. To be clear, by decision making we mean the type of active, option-weighting, high-level processing that was studied in the work by Schmeichel et al. (2003). Willfully engaging in control over oneself would seem to naturally relate to exerting control over the environment in the form of making choices.

Extant findings suggest that although people generally like the idea that they have control over their life outcomes, at the time same people may find making choices onerous. Consider, for example, the coffee company Starbucks. In 2003 Starbucks boasted that each store offered consumers over 19,000 beverage "possibilities" and that the number was growing with the introduction of their new superheated option. Contrast Starbucks' underlying assumption (that more options are good) with the now-seminal work by Iyengar and Lepper (2000) who showed that shoppers who were given 24 varieties of jam, as opposed to six varieties, were less likely to buy jam at all and were more dissatisfied when they did make a purchase. The rational choice model would likely say that having more options is better for consumers because each option increases the potential for preference-matching. Although this may be true relative to conditions under which no options are available, more likely is that people today view the proliferation of choice with distress, resulting in what Schwartz (2000) refers to as "the tyranny of freedom." Hence, Vohs and colleagues set out to test whether active decision making renders ensuing self-control less successful due its debilitating effect on ego resources. Their research included eight studies that converged on the conclusion that making choices depletes self-regulatory resources.

In one study participants made a series of binary choices between different versions of household products. For instance, participants in the choice condition were asked to choose between different colors of t-shirts, different colors of socks, and differently-scented candles. Participants in the no-choice condition were asked to give their opinions on eight advertisements taken from popular magazines. Thus, participants in both conditions were asked to evaluate the stimuli and engage in detailed thought processing, but only in the binary choice condition did participants render a decision. For the second task, participants were taken to a second room with a new experimenter and asked to hold their arm in a tank of freezing cold water for as long as they could (the cold pressor task). As would be predicted on the basis of a limited-resource model of self-control, participants who had previously made decisions were less able than were participants who had not had to make choices to keep their arm submerged in icy cold water. A second experiment that also used this manipulation found that participants in the choice condition, as opposed to no-choice condition, procrastinated longer when they could have been studying for an upcoming intelligence test.

In two additional studies, participants made decisions about the course in which they were currently enrolled, or they simply evaluated similar aspects of the course. Afterwards, they attempted to solve unsolvable puzzles (in one study) or were asked to perform mathematic problems (in another study). In line with the previous findings, these experiments showed that participants who made decisions about how the course should be run persisted less at the subsequent puzzle, as well as attempted fewer math problems and got fewer correct, as compared to participants who only evaluated aspects of the course.

There were several confounds with the laboratory experiments, namely the idea that being in the choice condition primed the idea of choices, which led to participants in that condition being more aware of their ability to choose to stop the second task. To get around that alternate explanation, Vohs et al. went to a local mall and asked shoppers to complete a questionnaire about how much they had made choices throughout their shopping trip that day. Then they asked the same shoppers to complete as many 3 digit + 3 digit addition problems as they could. A second experimenter surreptitiously recorded the length of time spent on the math problems, and this measure in addition to number of problems attempted was the indicator of self-control ability. As expected, shoppers who said that they had made many active choices were less persistent at the math problems, both in terms of number of problems attempted and duration, than were shoppers who said they had made fewer choices. This effect held even when statistically controlling for amount of time spent shopping and other pertinent variables such as age and gender. Given that all shoppers were exposed to the same scale that would have primed them with the same choice-related concepts, it is unlikely that a simple priming effect could explain the naturalistic experiment. In other words, this field study showed that compared to consumers who had made fewer choices during their shopping trip, those who had made multiple choices were less able to engage in the self-control needed to persevere at tedious math problems in the middle of a shopping mall.

In short, because the executive aspect of the self is involved in both decision making and controlled processes, the two functions are intimately related. This interrelation means that when one is engaged, the other is later impaired. The assumption is that self-regulatory resources grease the wheel for both decision-making processes and controlled processes to operate smoothly. If there are fewer self-regulatory resources due to decision making, self-regulation will be crippled; and, as we saw earlier, if there are fewer self-regulatory resources because of more basic acts of self-control, decision making will be poorer. Studies showing how easily goal attainment can be thwarted hint at the preciousness and fragility of self-regulatory resources.

SUMMARY

Setting standards or goals is the first important step in self-regulation. If people see that their current state is discrepant from their desired goal state, they may engage in behavior to try to meet their goal. In order to be effective at producing behavior change, goals should be specific, consistent, and attainable. People need to be motivated to change, and see themselves as capable of changing, in order for effective self-regulation to occur.

Not only does one need to have standards for self-regulation, one needs to monitor one's progress toward meeting those standards. Monitoring involves being aware of the self's behavior or responses and comparing them to the standard. Keeping track of one's purchases by keeping a running total of the dollar amount spent is an example of monitoring one's consumer spending. Monitoring allows people to assess distance to the goal. Effective monitoring requires accurate and reliable feedback about one's progress toward the goal. A breakdown in monitoring is a key reason why goals are not met, and improved monitoring is one of the best ways to improve self-control in all spheres.

Even if a consumer has specific, consistent, and appropriate standards and monitors his or her behaviors, the goal will not necessarily be met. Willpower or self-control strength is necessary to bring behavior in line with the standard. Self-control functions like a muscle that can be depleted with use but strengthened over time. Self-regulation is governed and limited by a finite supply of energy or strength that is used for all controlled responses and actions (as well as for other executive functions, such as making choices). Engaging in one self-control task leaves less energy available for subsequent self-control tasks.

Self-control can affect consumers in areas as varied as eating, spending, and making choices and decisions (including purchasing decisions). If people have to restrain their eating when they are hungry for dietary or other reasons, they use some of their self-control energy and thus have less of this resource available subsequently to engage in other self-control tasks. Likewise, people who engage in initial acts of self-control may be less able to control their eating. People whose self-regulatory capacity is reduced by engaging in self-control tasks of various kinds are more likely to make subsequent impulsive purchases and to choose self-indulgent products than people whose self-control was not depleted.

Self-regulatory resource depletion brought on by brief acts of self-control was found to impair intelligent thought and shift decisions toward simpler, lazier, and more superficial styles of decision making. This research implies that decision making is more than just a function of opportunity or willingness; decision making is also executive functioning ability. Not only does engaging in self-control affect subsequent decision making, but decision making can affect self-control as well. Active decision making can render subsequent self-control less successful due to its depleting effect on self-regulatory resources. Self-regulatory resources provide the energy for both active decision making and a wide variety of self-control tasks.

NOTES

1. Although the original research compared obese versus nonobese consumers, Herman, Olmstead, and Polivy (1983) revolutionized research on eating with their insight and empirical data showing that chronic dieting is the driver of most of the effects found between obese and nonobese participants, due to the fact that the obese people were very often chronically dieting. When the analyses were conducted using restrained eaters (the technical term for chronic dieters) versus nonrestrained eaters, this distinction captured the lion's share of the variance in terms of past research on obese versus nonobese participants.

Goal-Directed Consumer Behavior

Motivation, Volition, and Affect

HANS BAUMGARTNER

Pennsylvania State University

RIK PIETERS

Tilburg University

Consumer behavior, like other human endeavors, is unmistakably goal-directed. As Aristotle (1953, p. 3) said, “every act and every investigation, and similarly every action and pursuit, is considered to aim to some good,” with the final aim of goal-directed behavior being happiness. “Happiness, then, is found to be something perfect and self-sufficient, being the end to which our actions are directed” (Aristotle, 1953, p. 15). Yet, between the daily activities of consumers and the ultimate ends to which they aspire there is a vast terrain in which more specific and mundane goals and affect provide direction and energy to behavior. It is this terrain that the present chapter explores. That is, we focus on the motivational and volitional properties of goals and the interplay between goals and affect in consumer behavior.

Proposing that consumer behavior is goal-directed seems like arguing that water is wet. Surprisingly, however, even though motivational and volitional concepts abound in the marketing literature, systematic research on goal-directed consumer behavior has been lacking. To be sure, researchers have investigated issues related to consumers’ pursuit of goals. For example, both abstract goals such as values (Kahle, Beatty, & Homer, 1986; Kamakura & Novak, 1992) and concrete goals important in decision making and information processing (Bettman, 1979; Bettman, Luce, & Payne, 1998; Keller, 1987; see also Fishbach & Dhar, this volume) have been examined. If behaviors such as the purchase of routine products are thought of as the pursuit of simple, unproblematic goals, then attitude-behavior models may be interpreted as models of goal-directed behavior. In fact, these models have often been applied to situations in which the behavior is actually a more long-term, complex goal, such as losing weight (see the review by Sheppard, Hartwick, & Warshaw, 1988). In general, however, understanding goal-directed consumer behavior has not been emphasized in consumer research.

Research on affect has a longer tradition in the study of consumer behavior (Bagozzi, Gopinath, & Nyer, 1999; Cohen, Pham, & Andrade, chapter 11, this volume). However, despite the clear linkages between the goals of consumers and the affect they experience, there is little literature on the interface between affect and goal-directed behavior (Bagozzi et al., 2001).

In this chapter, we attempt to integrate research on goal-directed consumer behavior with relevant work on affect, and offer a model of goal pursuit and the functions that affect plays in goal setting and goal striving. The chapter focuses on goals that are selected in a reflective manner and pursued consciously, although we acknowledge that there are important and frequent automatic, nonconscious influences on goal pursuit (Chartrand & Bargh, 2002; see also Fishbach & Dhar, chapter 24, this volume). We start with a discussion of important issues related to goals and goal-directed behavior in general. We then turn to affect, distinguishing between endogenous (integral, task-relevant) and exogenous (incidental, ambient) affective influences and considering various functions of affect in goal pursuit.

GOAL STRUCTURE

Goals are internal representations of desirable states that people try to attain and undesirable states that they try to avoid. Goals differ from other motivational constructs, such as needs and drives, because they tend to be more concrete and domain-specific, thus exerting a stronger influence on particular consumer behaviors. Although, in the final analysis, high-level goals, such as trying to be independent, converge with terminal values, such as the importance of freedom, goals normally differ from values because they direct and energize behavior actively, rather than merely providing abstract evaluative criteria for appraising objects, events, or actions. Goals are relevant if an attempt to attain a desirable state can fail, or if consumers need to sacrifice something in order to get what they want. Turning off the air conditioner is usually not a goal but an act, but it becomes a goal when it is steaming hot outside and the consumer desires to be environmentally friendly. Following other goal theories, we assume that many of the interesting consumer behaviors are organized around the pursuit of goals, that goals are hierarchically structured from lower to higher levels, that goal-directed behavior is characterized by effort expenditure and persistence in the face of temptations and interruptions, and that goals are accessible to conscious awareness, although they need not always be top-of-mind during goal pursuit (Austin & Vancouver, 1996; Emmons, 1996; Locke & Latham, 1990). Before discussing how goal pursuit takes place, we examine goal features and goal structure. First, we discuss several goal features that characterize and distinguish the goals that consumers pursue. Second, since goal-directed behavior usually involves many different goals at varying levels, we describe how goals are organized.

Features of Goals

Individual goals have several features that give them meaning and account for their influence on behavior, and also distinguish them from each other (Austin & Vancouver, 1996; Emmons, 1989; Little, 1983; Winell, 1987). We will briefly discuss the features of goal content, desirability, importance, and feasibility.

Goal content. Goal content refers to what it is that consumers pursue. Several classifications of general or domain-specific goals or goal categories have been proposed, the only restriction being an author's creativity and drive toward completeness or generality. Winell (1987), for instance, distinguishes goals related to different life domains such as career, family, social/community, leisure, and material/environment. Emmons (1996) lists 12 general categories of goals, including achievement, affiliation/intimacy, power, independence, and self-presentation. Kasser and Ryan (1993, 1996) identify intrinsic (e.g., affiliation and personal growth) and extrinsic (e.g., power, materialism) goal orientations that are reflected in more specific goals. In the most general sense, goals may be approach-oriented (e.g., start an investment program) or avoidance-oriented (e.g., stop smoking).

Goal desirability. Because goals are internal representations of desired states to be attained or undesirable states to be avoided, the desirability of a goal is an important motivational dimension. Although avoidance goals focus on undesirable states, successful pursuit of these goals can be highly desirable, and some goals are more desirable than others. In expectancy-value theories of motivation (Heckhausen, 1977; Kuhl, 1982), value, utility, valence, or incentive are often used to capture a goal's desirability. The affect associated with a goal is an important determinant of goal desirability, and this issue will be discussed in greater detail below.

Goal importance. Goal importance is a related but different dimension. That is, goals may be highly desirable, such as having the right salad dressing, but not very important in the larger scheme of things. The distinction between goal desirability and importance is analogous to the distinction between the valence and strength dimensions of attitudes (Petty & Krosnick, 1995). Goal importance and the closely related notion of commitment are considered to be antecedents of the amount of effort expended on goal pursuit and the persistence of goal-directed behavior, and they have been linked to consumer involvement (Celsi & Olson, 1988), defined as the personal relevance or importance of a situation or task to a consumer's goals. One way to conceptualize importance is as the discrepancy between the current state of affairs and a desired state. The greater the discrepancy is perceived to be, the more important the goal is expected to be to the person. Commitment to the goal is particularly important when people do not freely choose their goals, but the goals are assigned to them (e.g., in work settings), and when goal pursuit is difficult and takes place over extended periods of time (e.g., losing weight or saving money for a new home).

Goal feasibility. In general, feasibility is a consumer's perception of control over whether or not a goal can be achieved (see Skinner, 1996). Constructs subsumed under this term include various forms of expectancies, probability of success, confidence, self-efficacy, controllability, and ease or difficulty of goal achievement.

Skinner (1996) proposed a useful distinction between agents (the person exerting control), means (pathways through which control is exerted), and ends (outcomes over which control is exerted) of control, and classifies the various control constructs found in the literature by whether they refer to agent-means, agent-ends, or means-ends relations. Agent-means relations are beliefs held by agents that they can use certain means. Examples of these beliefs are Bandura's (1977) self-efficacy expectations, Vroom's (1964) expectancies, Heckhausen's (1977) action-outcome expectancies, and Ford's (1992) capability-based personal agency beliefs. Agent-ends relations are beliefs held by agents that they can attain desired and avoid undesired outcomes. Evaluations of the probability of goal success and goal failure, the perceived ease or difficulty of goal attainment, and confidence in one's ability to attain a particular goal belong in this category. Skinner also argues that Bandura's later writings on self-efficacy (Bandura, 1989) place the construct in this group. Finally, means-ends relations are beliefs that certain causes (internal vs. external causes, actions vs. attributes of agents, etc.) will lead to desired or undesired outcomes. Rotter's (1966) locus of control, Vroom's (1964) instrumentalities, Bandura's (1989) response-outcome expectations, Heckhausen's (1977) outcome-consequence expectancies, and Ford's (1992) context-based personal agency beliefs are examples that fit this description.

Organization of Goals

Goals are organized in semantic networks, with goals and their means as nodes and the relationships between them as linkages. Although goal structures are latent, hypothetical constructs, we can distinguish horizontal and vertical dimensions in them. The horizontal dimension in goal structures represents the degree of similarity, relatedness or conceptual overlap between goals, based on goal content. Thus, related goals will tend to be closer together, because they share similar

higher-level goals and lower-level means. The vertical dimension reflects the hierarchical organization of goals. The idea is that goals are hierarchically organized from lower-level, subordinate, more concrete means to higher-level, superordinate, more abstract ends (Bandura, 1989; Carver & Scheier, 2000; Hacker, 1985; Little, 1989; Locke, 1991; Powers, 1973; Vallacher & Wegner, 1985). The vertical location of goals in the hierarchy relative to other goals reflects their abstractness or specification level.

Goal abstractness. Concrete goals are generally more perceptual, observable in nature, referring to specific ways in which a desired state can be accomplished. An example would be the goal of eating smaller portions at lunch and dinner as part of a dieting plan. Abstract goals embody high-level motivational concerns that do not provide specific guides to behavior but indicate what the individual wants to be. The most abstract goals are not restricted to a particular domain and have motivational relevance for many different behaviors. Values are prime examples of abstract goals. The consumer behavior literature has explored low-level, domain-specific goals for advertising processing and decision-making and high-level goals such as values that guide consumption decisions in an abstract way.

In advertising, Pieters and Wedel (2007) distinguish four categories of processing goals that may be active during ad exposure, depending on the goal target (brand vs. ad) and goal content (learning vs. evaluation), based on the work of Keller (1987) and Dweck and Leggett (1988). They point out that most advertising theory is devoted to brand evaluation goals (as in dual process models such as the elaboration likelihood model), which cover a single quadrant of their conceptual model, and they show that once activated each of the goal categories rapidly affects advertising processing in systematically different ways.

In decision making, Bettman, Luce, and Payne (1998) consider four decision-making goals underlying choice processing: maximizing decision accuracy; minimizing decision effort; minimizing negative emotions during decision making; and maximizing the ease of justification of a decision. In attitude research, it is all too frequently assumed that people are motivated to hold accurate attitudes, although more recently other goals have been considered as well, such as the goal to hold attitudes that are congruent with core aspects of the self-concept (defense motivation) or the goal to express attitudes that have desirable interpersonal consequences (impression motivation) (see Chaiken, Wood, & Eagly, 1996). These decision-making goals may govern decisions independently of the specific life goals that consumer pursue. That is, during goal pursuit consumers need to make decisions between alternative courses of action, which may be influenced by various decision-making goals, in order to attain particular, more abstract life goals. However, it is clear that decision-making goals are at a relatively low level of abstraction in the goal hierarchy, particularly if one considers how they have been studied in empirical research (e.g., choosing among three cars described with numerical ratings on two attributes, ride quality, and miles per gallon).

In contrast, research on values can be viewed as investigating goals at a very high level of abstraction (Kahle et al., 1986; Kamakura & Novak, 1992). Much work on values has been concerned with investigating the structure of values, and the studies that have tried to relate values to actual behavior have generally shown very modest success. However, it should not be too surprising that goals at the highest level will not predict specific consumption behaviors very well, and means-end chain theory (Reynolds & Olson, 2001) was developed to make the linkages between values and consumption behaviors (in the form of preferences for certain product attributes) more explicit.

Three fundamental goal levels. The abstractness or specification level of a goal can be considered as a continuous characteristic, and goal research has applied quantitative measures to assess abstractness in goal structures (Pieters, Baumgartner, & Allen, 1995). Qualitative differences in the role and meaning of various levels of goals have been proposed as well.

For instance, Huffman, Ratneshwar, and Mick (2000) developed a hierarchical model of consumer goal structure that ranges from the most abstract goals such as life themes and values via life projects, current concerns, consumption intentions, and benefits-sought to feature preferences. As stated by these authors (p. 20), “we [as consumers] *acquire* possessions to *perform* actions that move us closer to *realizing* our values and ideal selves.” In this way, the levels in the hierarchy link “having” to “doing” and ultimately to “being” goals.

We have found a different conceptualization of consumer goal structures useful (Pieters, 1993; Pieters, Allen, & Baumgartner, 2001; Pieters, Baumgartner, & Allen, 1995). Our framework is most closely related to Little’s (1983, 1989) work on personal projects, Emmons’ (1996) research on personal strivings, and Vallacher and Wegner’s (1985) action identification theory. We distinguish three levels of goal-directed behavior: the “what” or identification level; the “why” or motivation level; and the “how” or operation level (see the left panel of Figure 13.1). The “what” level is the level at which goal pursuit is initially considered and it is the level at which a goal is set or a goal intention is formed. It is the basic level in the goal hierarchy, that is, the specific goal a consumer is currently pursuing. For example, in the domain of weight control, the “what” level generally involves the decision to lose body weight. Deciding to lose weight might entail more specific deliberations about how much weight to lose within a certain time frame, but the essence of goal setting is the formation of an intention to lose weight. The goal at the “what” level coordinates the execution of the lower-level goals at the operation level, whose attainment is needed to achieve the basic-level goal, and it is itself motivated by higher-level goals, which provide the ultimate meaning for why the goal is pursued.

Goals below the identification level may be called “how” goals because they indicate what has to be done in order to achieve the basic-level goal. With very simple behaviors aimed at relatively low basic-level goals, the operation level may be relatively undifferentiated or not even reach conscious

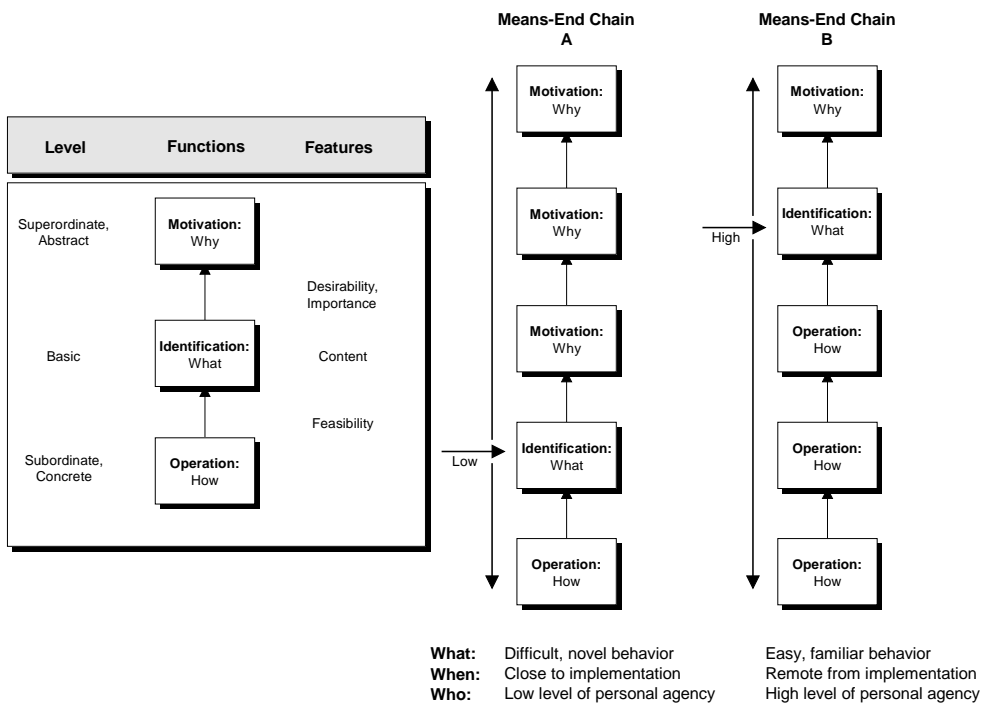

Figure 13.1 A model of goal level flexibility

levels of awareness, but in other cases it will consist of potentially many levels, at each of which distinct goal setting and goal striving processes take place. For example, in order to lose weight consumers can diet or exercise, and many specific decisions are involved in deciding how to diet or how to exercise.

Following action identification theory, we argue that there is an optimal level at which goal-directed behavior is identified, and that the level at which goal-directed behavior is identified may change depending on various factors such as the novelty and difficulty of the action, the time to goal implementation, and individual differences (see Vallacher & Wegner, 1989, on “levels of personal agency,” and Emmons, 1996, on low-level versus high-level strivers). For example, the more difficult and novel the action is, and the closer the person is to goal implementation, the lower the abstraction level at which the action is identified. On the other hand, the more remote, easy and familiar the action, the higher the abstraction level. Furthermore, since lower-level behaviors can be components of many different higher-level actions, an initial move to a lower level (e.g., due to difficulties encountered during the enactment of a certain behavior) and a subsequent return to a higher level (because people attempt to control their behavior at the highest possible level) may lead to the emergence of entirely new actions (Vallacher & Wegner, 1987). In practice, it is not clear how often this will actually occur, and even though conscious control of behavior may shift to lower levels when difficulties are encountered, our framework assumes that the stream of goal-directed behaviors is ultimately controlled by the basic-level goal. Of course, the basic-level goal need not always be top-of-mind, and sometimes it will be nonconscious.

Goals above the identification level are “why” goals because they usually provide the motivation for pursuing the basic-level goal. Sometimes, when the basic-level goal is intrinsically motivating (e.g., spending a fun afternoon at the amusement park), there is little reason for studying superordinate goals, and such goal-directed behavior could be called consummatory rather than instrumental, since its execution is the only goal. However, frequently basic-level goals acquire their motivating potential through their association with higher-level goals. For example, losing weight is unlikely to be an intrinsically desirable goal. People desire to lose weight because they want to lead a long and healthy life, because they want to feel good about themselves, or because they want to be attractive and socially accepted by others. Thus, in order to understand what motivates goal pursuit and ultimately leads to a decision to try to attain the basic-level goal, one has to know what the “why” goals underlying a “what” goal are and how desirable they are to the consumer. In this sense, “why” goals endow goal-directed activities with meaning.

The idea of a three-layered goal hierarchy clarifies the goal features of desirability, importance and feasibility, because goal desirability and importance derive from the linkages of the basic-level goal to the superordinate goals at the motivational level, while feasibility derives from the linkages of the basic-level goal to the subordinate goals at the operation level.

The proposed three-layered goal hierarchy also emphasizes the crucial importance of goal identification because the motivation and operation of goal-directed behavior depend on how the goal is identified. In other words, “why” and “how” consumers do what they do depends on “what” they are doing. Consumers who “try to be environmentally friendly” (identification) may do so by “buying environmentally products” (operation) in order to “be good citizens” (motivation). On the other hand, consumers who “try to be good citizens” (identification) may do so by “being environmentally friendly” (operation) in order to “feel good about themselves” (motivation). This shows that the three goal levels are mutually dependent because motivation for one consumer or situation may be identification for another, as the right panel of Figure 13.1 indicates.

Means-end linkages. The hierarchical organization of goal structures in terms of the three goal levels, and the abstractness of the individual goals in the structure, are due to specific relationships

between goals and behaviors, so-called means-end linkages, which form the fabric of goal structures. We distinguish several such linkages (see Emmons, 1996; Pieters, 1993; Pieters et al., 2001; Shah, Kruglanski, & Friedman, 2003). First, there can be vertical relations between goals at different levels in the hierarchy. For example, a consumer may want to lose weight in order to look more attractive, or exercise because of the belief that this is an efficient means of losing weight. We call such means-end linkages *instrumentalities*, because elements at lower levels in the hierarchy serve as means to achieve elements at higher levels as ends. If a single lower-level goal is connected to a single higher-level goal, ordinary instrumentality is present. Since consumers can also do different things simultaneously, each behavior for its own reasons, it is possible that several ordinary instrumentalities co-exist, a form of *parallel finality*. This occurs, for instance, when consumers entertain friends while cooking, shop while baby-sitting their neighbors' children, or eat while reading. Commonly, a given lower-level goal is associated with multiple higher-level goals, or several lower-level goals all lead to a single higher-level goal. In the former case we speak of *multifinality*, in the latter case of *equifinality*. For example, a consumer who sees physical appearance as instrumental to both personal confidence and social acceptance illustrates multifinality. In contrast, a consumer who pursues both dieting and exercising in order to lose weight exemplifies equifinality. When the multiple outcomes of an act are dissonant, rather than consonant as in multifinality, goal conflicts arise, as discussed later.

Second, there can be horizontal relations between goals at the same level of the hierarchy. For example, buying a washing machine may involve a sequential process in which information on various brands and their attributes is collected first, some decision rule is used to make a choice, and then the chosen brand is actually purchased at some store. Although one could argue that all three behaviors are instrumental for attaining the purchase goal, the difference is that each step is conditional on the previous step. Furthermore, it is probably more natural to think of the three behaviors as occupying the same level in the goal hierarchy. One might refer to such relations as *sequential finality*. Sequential finality introduces time and sequences of behavior (scripts and programs) that need to be executed in some order or combination as an explicit influence on goal pursuit. Goal structures represent consumers' knowledge of how and why to attain specific goals (Shah, Kruglanski, & Friedman, 2003), containing specific as well as more generalized knowledge of goal attainment, such as generalized scripts, which are typically comprised of sequential finality components. Bettman (1979) was one of the first to extensively discuss and use goal hierarchies in his information processing theory of consumer choice. For example, he considered how lower-level goals such as buying a washing machine can be broken down into more specific subgoals that are accomplished sequentially over time in pursuit of the overarching goal.

The five means-end linkages, shown graphically in Figure 13.2, jointly form the building blocks of goal structures. In the case of (simple) instrumentality, there is a single means-end linkage without branching. In the case of equifinality and sequential finality, there is a single goal and multiple means, and, in the case of multifinality and parallel finality, there are multiple goals and one or more means. Goal structures become activated during goal pursuit, as explained next.

GOAL PURSUIT

Goal pursuit unfolds over time and space. Following several comprehensive models of the processes involved in goal pursuit (Carver & Scheier, 2000; Gollwitzer, 1990; Heckhausen, 1991; Locke & Latham, 1990), we distinguish between two subprocesses: goal setting and goal striving. Goal setting is a motivational process during which a consumer has to decide whether or not to pursue a given goal, or chooses between conflicting goals. Goal striving is a volitional process concerned

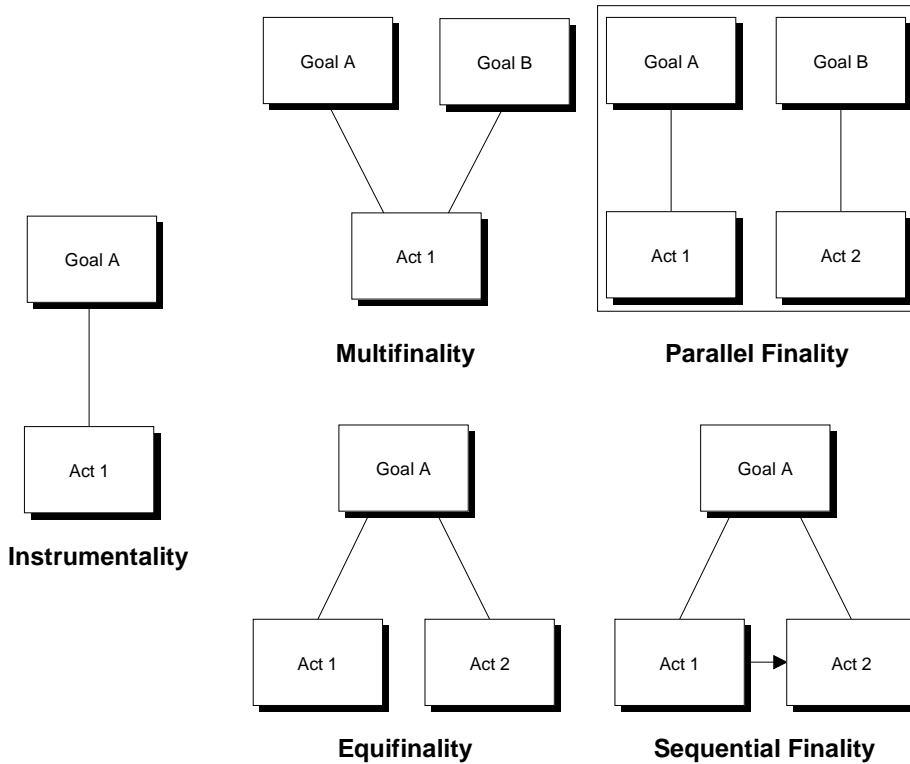

Figure 13.2 Components of goal structures

with working toward the chosen goal (Heckhausen, 1991). The distinction is old (Lewin, Dembo, Festinger, & Sears, 1944), but has been found useful by many authors over the years (see Bagozzi & Dholakia, 1999; Gollwitzer, 1990; Heckhausen, 1991; Oettingen & Gollwitzer, 2004). Table 13.1 summarizes goal setting and goal striving processes, and the specific activities involved in each.

Goal setting and goal striving processes occur at different levels in the goal hierarchy, and goal setting determines but is also determined by goal striving. For example, a consumer who has decided to lose weight and is working toward this goal has to make further decisions about whether to diet or exercise. If she decides to focus her efforts on exercising, still further decisions have to be made about which exercise regimen to adopt. Thus, it may seem difficult to separate the two processes since they are so heavily intertwined. To some extent this is the case. However, it is also true that the psychological problems involved in goal setting and goal striving are quite distinct (making a decision to pursue a certain goal and choosing between alternative goals in the case of goal setting versus planning, initiating action, monitoring progress, dealing with obstacles, and evaluating goal achievement in the case of goal striving). Furthermore, goal setting is presumably most important when a consumer makes the initial decision to pursue a particular goal, which we call the basic or identification level of goal pursuit, and our discussion of goal setting is mostly focused on this issue.

Goal Setting

Setting a goal refers to the processes involved in representing a desired state internally with the intention of reaching this state, including selecting a goal from among its alternatives (dieting vs.

Table 13.1 Goal Pursuit and Functions of Affect

Stage	Focus	Goal pursuit activities	Functions of affect

reducing debt), as well as committing oneself to a specific level to attain (lose 10 lbs. in the next 6 months or 4 lbs. in the next 4 weeks). The outcome of the goal-setting process is a goal intention, a self-instruction to strive toward attaining the desired state, which provides overall direction to goal pursuit and commits the person to trying to attain the desired state (Gollwitzer, 1990). But how does a consumer decide to pursue a particular goal?

As a first step, let us distinguish between external and internal goals (Austin & Vancouver, 1996). Although all goals are ultimately internally represented, some goals are motivated by external factors and other goals by internal ones. The prototypes of external goals are assigned goals, which have been studied extensively by industrial psychologists (Locke & Latham, 1990). Examples in a consumer behavior setting are buying “commissioned gifts” for weddings or similar occasions, dieting on the advice of the doctor, buying groceries with someone else’s list, and so forth. We focus on internal goals (i.e., goals that are pursued primarily for personal reasons), but acknowledge that external factors can have a significant influence on goal pursuit (Fishbein & Ajzen, 1975). We also emphasize deliberate goal-setting processes, although goals may become activated incidentally, for example during exposure to means with strong linkages to higher-level desirable goals (such as when exposure to an ad for a low-fat product primes a weight loss goal). Such bottom-up goal priming effects have obvious relevance for consumer behavior (see Fishbach & Dhar, chapter 24, this volume).

Expectancy-value theories of goal setting. Consumers usually face a multitude of wishes that cannot all be enacted. One source of these wishes is the marketing environment, which is designed to arouse desires in consumers and encourage wish fulfillment. How do some wishes get transformed into goals that the consumer wants to attain (buying a Ford), while others remain mere fantasies (driving around in a Ferrari)? The general principle of expectancy-value theories is that the more desirable the goal, the higher the likelihood that it will be chosen, but the consumer also has to believe that goal achievement is feasible. There is a long tradition of expectancy-value models of motivation, starting with the work on level of aspiration (see Lewin et al., 1944, for a review), but the models that have had the greatest influence on the consumer behavior literature

are two attitudinal theories, the theory of reasoned action (Fishbein & Ajzen, 1975) and the theory of planned behavior (Ajzen, 1985).

The theory of reasoned action (TRA) was originally designed to explain and predict volitional behaviors (e.g., using birth control pills or donating blood), which may be thought of as very simple goals, in the sense that goal pursuit is not problematic. However, the theory has often been applied to goals rather than behaviors (e.g., losing weight). TRA can be regarded as a theory of goal setting because the essence of the model is how people form intentions to engage in a behavior or pursue a goal. According to TRA, behavioral intentions are a function of a personal factor, attitude toward the behavior, and a social factor, subjective norms. Attitudes are conceptualized as the summation of a person's evaluation of the consequences of engaging in the behavior weighted by his or her beliefs that the behavior will lead to these consequences. The consequences have generally been rather cognitive in nature, although they could include affective experiences (e.g., guilty feelings or increased sexual pleasure as consequences of using birth control pills, as in Jaccard & Davidson, 1972), and they are usually rated on semantic differential scales such as good–bad. In the terminology used earlier, the belief strength ratings are similar to instrumentalities or outcome-consequence expectancies, and the evaluations measure the desirability of the consequences associated with the behavior.

Ajzen (1985, 1991) proposed the theory of planned behavior (TPB) as an extension of TRA to deal with situations in which a person does not have complete volitional control over the behavior (i.e., a person cannot decide at will whether or not to perform the behavior). Ajzen argues that in such cases perceived behavioral control (i.e., the perceived ease or difficulty of performing the behavior, which reflects goal feasibility) serves as an additional determinant of intentions and possibly behavior. Research shows that the inclusion of perceived behavioral control generally improves the explanation of intentions and actual behavior and that perceived behavioral control has unmediated effects on behavior when perceptions of control are low (Ajzen, 1991; Madden, Scholder-Ellen, & Ajzen, 1992). Ajzen (1991) argues that perceived behavioral control closely corresponds to self-efficacy beliefs, but the empirical measurement of this construct frequently includes aspects of situation-outcome expectancies as well (e.g., the number of events outside people's control which could prevent them from engaging in the behavior are numerous or few).

Bagozzi and Warshaw (1990) proposed a theory of trying (TT), which describes the determinants of consumers' attempts at goal attainment. The theory is similar to Ajzen's (1985) model but includes influences of past behavior (frequency and recency), although this aspect of the theory is less relevant here. Bagozzi and Warshaw argue that when behaviors are not under complete volitional control, the relevant dependent variable is not behavior but attempts to achieve the goal (i.e., trying). Trying is a function of intention to try (as well as the frequency and recency of past trying), which in turn depends on attitude toward trying and social norm toward trying (as well as the frequency of past trying). Attitude toward trying is determined by attitude toward success, weighted by expectation of success, attitude toward failure, weighted by expectation of failure, and attitude toward the process of trying. Attitudes toward success, failure and process are specified as multiplicative functions of the likelihood of various consequences and their evaluation. The findings of a study on weight loss supported the model, except that attitude toward failure and expectations of failure did not influence attitude toward trying. Note that expectations of success and failure are meant to represent self-efficacy beliefs by Bagozzi and Warshaw.

Although the theories of reasoned action and planned behavior have been extremely popular as models for explaining and predicting behavior and have frequently been applied to goals, they were not designed to be goal-setting models. The theory of trying was explicitly proposed to deal with goals, but empirical tests have been limited. In general, conceptualizations of the desirability

of behaviors and goals have been based on an expectancy-value model, but in empirical applications researchers have left it to the participants to determine whatever outcomes or consequences are relevant to the behavior in question. Furthermore, feasibility considerations have only been incorporated into these models in a very rudimentary way, for instance as perceived behavioral control. Verhallen and Pieters (1984) proposed to include the mental, physical and time costs of goal pursuit in attitude models of goal-directed behavior, in order to more fully capture the feasibility of goal attainment.

Goal conflict. Expectancy-value models of motivation assume that in case of multiple goals, the desirability and feasibility of each is determined, and that the highest scoring goal will be implemented in a “winner takes all” approach. Yet, consumers frequently experience goal conflicts (Baumeister, Heatherton, & Tice, 1994; Emmons, 1996), either due to ambivalence or goal incompatibility. First, ambivalence may be experienced in case of an approach-avoidance conflict, when a goal simultaneously combines desirable and undesirable outcomes, such as when a person strives to lose weight during a Sunday BBQ at the lakeside. Second, two highly desirable goals may compete for the same resources, leading to an approach-approach conflict. For example, a consumer may want to take a year-long world cruise but also build a house. Similarly, two desirable goals may be intrinsically conflicting, leading to an approach-approach conflict due to a value restriction. For example, consumers’ religious values calling for a life of material simplicity may conflict with their material values (Burroughs & Rindfleisch, 2002). Comparatively little is known about the frequency, determinants and consequences of goal conflicts, and how consumers resolve them.

Goal Striving

Once a decision has been made to pursue a goal (i.e., a goal intention has been formed), the consumer has to consider the implementation of the chosen goal: possible courses of action have to be planned, actual goal-directed behaviors have to be initiated and maintained, progress has to be monitored and possible adjustments have to be made, obstacles have to be dealt with, and, finally, goal achievement has to be evaluated. Almost no research on these issues is available in the consumer behavior literature, and even in psychology literature, relevant research is of fairly recent origin. We will provide a brief overview of this work.

Planning. Planning means deliberating what has to be done in order to enact the chosen goal. As observed by Aristotle (1953, p. 58), “we deliberate not about ends but about means ... [people] first set some end before themselves and then consider how and by what means it can be attained. If it appears that it can be attained by several means, they further consider by which it can be attained best and most easily.” Planning thus involves thinking about how, where and when to act with the purpose of reaching the goal. Mental simulation about future outcomes and the courses of action to attain them yield plans that encourage goal achievement. Taylor and Pham (1996) distinguish outcome simulations (where only desired results are imagined) from process simulations (during which people imagine the steps involved in achieving a certain outcome) and show that the latter are more likely to lead to goal attainment.

An idea somewhat similar to mental simulation is Gollwitzer’s notion of implementation intention (Gollwitzer, 1993, 1996; Gollwitzer, Fujita, & Oettingen, 2004). Gollwitzer argues that when goals are simple and enactment has been habitualized, goal intentions may be sufficient to bring about successful goal achievement. However, when implementation is not a matter of routine and the person is having difficulties getting started, implementation intentions may have beneficial effects. An implementation intention is a self-instruction to execute a particular goal-directed behavior “automatically” when a certain situation is encountered (i.e., I will do x when situation

y arises). Implementation intentions are expected to promote successful goal pursuit for two reasons. First, they heighten the salience of the critical situation with which goal-directed behavior is associated. Second, they automate the execution of the relevant behavior when the critical situation is encountered. A recent field experiment by Kardes, Cronley, and Posavac (2005) in a marketing context illustrates these benefits. All study participants received a free sample of a household liquid cleaning product to take home. Half of the participants (those in the implementation intention condition) were asked to indicate the exact dates and times that they intended to use the product and the specific uses they had in mind, whereas the other half (those in the control condition) were only asked to indicate their intentions to use the product. An unexpected follow-up survey 2 weeks later revealed that participants used more of the product in a greater variety of different situations and formed more favorable attitudes and purchase intentions in the implementation intention condition than in the control condition.

Research so far has (a) shown that implementation intentions promote successful goal pursuit; (b) provided support for the processes assumed to underlie their volitional benefits, and (c) identified important moderators of their usefulness (e.g., goal difficulty, plan detail level). However, as acknowledged by Gollwitzer, in all of these studies participants were explicitly instructed to form implementation intentions, and we know little about if and when implementations are formed under self-generated goals. Furthermore, implementation intentions have usually been studied in contexts in which the goal was concrete rather than abstract, and we need to know more about intention formation and implementation in this latter, more realistic case. Moreover, overly specific plans and implementation intentions may backfire. For example, when a behavior is identified at a very low level and a person is focused on the operation (how) of the behavior rather than the attainment of the final goal (why), there may be little room for free choice and flexibility in the case of interruptions. In support of this, research (reported in Baumeister et al., 1994) shows that students who were instructed to formulate global, monthly plans for improving their study skills performed better and more persistently than students with detailed, daily plans.

Initiation and maintenance of goal-directed behaviors. Goal-directed behavior can be spontaneously triggered by the situational context (either because of previous experiences in which particular instrumental responses have been linked to certain environmental cues or because of previously formed implementation intentions) or deliberately initiated by the person. In the latter case, if the behavior is entirely under volitional control, goal pursuit is unproblematic. However, often one has to wait for an opportune moment to initiate action and maintain goal-directed behavior until it is completed. It has been proposed that a so-called implemental mindset, in which the focus of thought is on doing rather than on thinking, may help with this phase of goal pursuit (Gollwitzer, 1996; Gollwitzer et al., 2004). That is, after people have committed themselves to pursuing a given goal, they are presumably focused on information that is relevant to goal achievement and will tune out distracting information. Furthermore, information about the desirability and feasibility of the chosen goal will be processed in a biased fashion so as to favor continued commitment and persistent goal pursuit.

Another important contribution to the literature on how people deal with difficulties in enacting goal intentions is Kuhl's (1984) work on action control. A central aspect of his theory is how the focal intention can be shielded from competing behavioral tendencies. The model assumes that action control motivation will increase when enactment difficulties are encountered, either due to internal reasons (competing action tendencies) or external reasons (situational features that are incompatible with the goal intention). A variety of action control processes are specified. First, selective attention directs processing to information favoring the goal intention, and encoding control leads to a focus on intention-relevant aspects of the stimulus. Second, emotion control

involves regulating one's emotions such that they are conducive to action implementation. Third, motivation control deals with biased processing of desirability and feasibility information. Fourth, environmental control means structuring the environment in such a way as to make it supportive of goal enactment. Finally, parsimonious information processing refers to limiting continued deliberation about action alternatives and initiating action execution. Kuhl has also proposed a personality variable called action- vs. state-orientation, which reflects whether or not a person is generally in an action-oriented mode of control, which favors the implementation of intentions, or a state-oriented mode, which favors reflection and deliberation.

Monitoring of progress. According to control theory (Carver, Lawrence, & Scheier, 1996; Powers, 1973), goal progress is monitored by feedback loops in which the consumer's current situation is compared to a reference standard (i.e., a goal). The implications of this comparison depend on the type of feedback loop. In a negative feedback loop, the goal is something to be approached. Therefore, a perceived discrepancy between the current situation and the goal requires adjustments to the current state. In contrast, in a positive feedback loop, where the goal is something to be avoided, the system is designed to enlarge the discrepancy between the current state and the avoidance goal. Carver and Scheier argue that positive feedback loops are generally unstable and are often constrained by negative feedback loops, such that a person trying to avoid an undesirable state eventually gravitates toward a more desirable state.

During reasonably complex goal pursuits many different goals at different levels of abstraction have to be monitored. Feedback loops can be specified at various levels of the goal hierarchy. The result of the comparison between the current state and a goal can be posited to serve as input to the establishment of a reference value (i.e., a goal) at a lower level of the hierarchy. In this way, an integrated monitoring system for the entire process of goal pursuit can be achieved.

Evaluation of goal achievement. People may hold outcome and process goals (Austin & Vancouver, 1996). With an outcome goal, goal pursuit is terminated when the goal has been reached (e.g., buying a car). With a process goal, goal pursuit is continuous since attaining the goal is not a discrete event and discrepancies are always possible (e.g., avoid making impulse purchases). In the latter case, successful goal pursuit does not lead to the termination of goal striving but attempts to maintain progress.

We distinguish four general coping strategies when evaluations of goal attainment are unfavorable (see Table 13.1). First, consumers can continue striving, working harder or longer (Baumeister et al., 1994). Second, an initial plan can be revised when assumptions made during planning turn out to be untenable or unforeseen circumstances occur. In this case, a new planning cycle starts that takes into account the new contingencies. Third, a goal can be postponed or tabled (Austin & Vancouver, 1996; Ford, 1992). Tabling means that the goal is temporarily put aside because of a preoccupation with a different goal favored by current circumstances. When this occurs, the question arises whether and under what conditions the original goal will be reinstated. Fourth, a goal can be abandoned when the likelihood of successful goal achievement is deemed too small. Stein, Trabasso, and Liwag (1993) and Oatley and Johnson-Laird (1996) have stressed the role of emotions in alerting people to aspects of goal pursuit that need attention and in orienting them toward possible courses of action. These issues are discussed in further detail below.

AFFECT AND GOAL SETTING

We use the term "affect" to refer to any type of valenced state, including emotions and moods, having experiential (thoughts, feelings), expressive (automatic and controlled) and arousal (autonomic nervous system) components (Frijda, 1986; Gross, 1998). We propose three functions of affect in

goal setting. First, the goal itself can be an affective experience, or the consequences resulting from goal achievement may be affectively charged. We call the former *affect-as-goal* and the latter *affect-as-motivation*. Both of these reflect endogenous affective influences. Second, the affect that is incidentally experienced at the time goal pursuit is deliberated may have an impact on goal setting. The nature of the affective influence is exogenous in this case, and we call it *affect-as-filter*. Third, setting certain types of goals can have implications for subjective well-being, which is a type of affective externality, and we call this *affect-as-hedonic spillover*. Thus, affect can be an integral part of goal setting (i.e., endogenous), it can be incidental to goal setting but influence it nonetheless (i.e., exogenous), or it may be an unintended consequence of goal setting (i.e., an externality). The third column of Table 13.1 summarizes these functions.

Influence of Endogenous Affect on Goal Setting

The most direct way in which affect can impact goal setting is when the goal itself is an affective experience (i.e., the desired outcome of goal-directed behavior is affective in nature or the process of goal pursuit is intrinsically pleasurable): *affect-as-goal*. Pervin's (1989, p. 474) definition of a goal, "a mental image or other end point representation associated with affect toward which action may be directed," makes this point very well. For example, a person might be guided by values of hedonism and stimulation and generally pursue experiences that are pleasurable and exciting (Schwartz, 1992). Less abstract goals might include spending a fun afternoon at an amusement park or watching a romantic comedy in a movie theater. These goals may be called consummatory (as opposed to instrumental), and research has confirmed that affect plays an important role in these types of decisions (e.g., Pham, 1998). Research also indicates that, in situations where affective and cognitive considerations are in conflict (e.g., a chocolate cake may be more affectively appealing than a fruit salad, but the cognitive consequences may be less favorable), choices are based on immediate affect when processing resources are limited, at least under certain conditions (Shiv & Fedorikhin, 1999; also see the chapter by Cohen et al., chapter 11, this volume, on the speed of affective processing).

Often, the process of goal pursuit is not pleasurable and even the goal itself is not intrinsically associated with affect. Nevertheless, a person may decide to pursue the goal because the act of goal achievement induces affect, or goal achievement is instrumental in reaching desired higher-level goals, which may be affectively charged. The affect experienced is not the goal per se, but the affective charge of attaining the goal influences goal setting, hence *affect-as-motivation*. Expectancy-value theories of motivation illustrate this perspective in a general sense, although they usually do not deal with affect directly. Goal choice in these models depends on the multiplicative combination of incentive (value) and likelihood of occurrence (expectancy or instrumentality). Although the incentive component may include affective experiences, any kind of outcome or consequence associated with the goal can have incentive value. For example, Heckhausen (1977) argues that self-evaluations such as feelings of pride and shame may serve as incentives for behavior.

Several attempts have been made to explicitly incorporate (anticipated) affect into expectancy-value models of behavior (see van der Pligt et al., 1998). The basic idea is that conventional models (e.g., the theories of reasoned action and planned behavior) only study evaluative responses based on beliefs associated with the behavior, but that people may also have anticipated affective reactions to the behavior or process (e.g., they may enjoy eating junk food) as well as anticipated postbehavioral affective responses (e.g., they may anticipate feeling bad after having eaten a lot of junk food). Thus, anticipated affect enters the goal setting stage in a way similar to mental simulation (Taylor & Pham, 1996). In an illustrative study, Richard, van der Pligt, and de Vries (1996) assessed evalu-

ations, affective reactions, and anticipated postbehavioral affective responses for four behaviors (eating junk food, using soft drugs, drinking alcohol, and studying hard) using the same semantic differential scales (pleasant-unpleasant, nice-awful, good-bad). They found that while evaluations and affective reactions toward the behavior were not empirically distinct, anticipated postbehavioral affective responses differed from both evaluations and affective reactions and had a unique influence on behavioral expectations, controlling for attitudes, subjective norms, and perceived behavioral control. Richard, van der Pligt, and de Vries (1995) obtained a similar finding for a more specific measure of anticipated postbehavioral negative emotions (worry, regret, and tension) in the context of behavioral expectations about HIV preventive behaviors. These findings illustrate the function of affect-as-motivation in goal setting.

A similar but more explicitly goal-based model was proposed by Baumgartner, Pieters, and Bagozzi (forthcoming). They draw a distinction between two types of future-oriented emotions, anticipatory emotions and anticipated emotions (see also Loewenstein et al., 2001; Loewenstein & Lerner, 2003). Anticipatory emotions are emotions that are currently experienced due to the prospect of a desired or undesired future event. The prototypes of these emotions are anticipatory excitement or hope in the case of positive future events and anticipatory worry or fear in the case of negative future events. Anticipated emotions, on the other hand, are based on imagining that certain desired or undesired events have already happened (possibly because of what one has or has not done) and then experiencing actual or imaginary emotions in anticipation of these simulated events.

There are several important differences between these two types of emotions. First, anticipatory emotions are currently experienced, veridical affective responses to possible future events that have positive or negative implications for the self, whereas anticipated emotions are based on pre-factual thinking about a future positive or negative event. They could be real emotional experiences, but may also function like affective forecasts (Gilbert et al., 1998). Second, anticipatory emotions are a subset of the complete range of discrete emotions that people can experience, namely, those related to the possible occurrence of future desired or undesired outcomes (i.e., hope and fear). Furthermore, the experienced emotion is generally either a positive or negative emotion, depending on the valence of the future event (unless the event is emotionally ambiguous). In contrast, any discrete emotion that can be experienced may be anticipated in advance, based on a mental simulation of future outcomes, and the anticipation of positive and negative future events can lead to the simultaneous experience of both positive and negative affective states. Third, since anticipatory emotions are current affective responses to the *prospect* of future events that have positive or negative consequences, uncertainty about what is going to happen constitutes part of the meaning of the emotion and is inseparable from the emotion (e.g., anticipatory hope in the case of desired events and anticipatory worry in the case of undesired events). In contrast, the likelihood of the focal event happening is a mental event distinct from anticipated emotions related to the event.

In a study dealing with the millennium transition (i.e., the so-called Y2K problem), Baumgartner et al. showed that positively and negatively valenced anticipatory and anticipated emotions were empirically distinct and that people who were fearful and experienced positive and negative anticipated emotions more intensely were more likely to form behavioral intentions aimed at averting possible negative consequences of the millennium change. Although goal intentions were not directly assessed in the study, intentions for a wide variety of behaviors were collected so that the measure is interpretable as the intensity of a person's goal to avoid or limit the expected problems caused by the millennium problem. This demonstrates how anticipatory and anticipated emotions can influence goal intentions, expressing the affect-as-motivation function. In Baumgartner et al.'s study, anticipated emotions were assessed as people's affective experiences to simulated goal

success and goal failure. However, more generally one might investigate how affect associated with the outcomes or consequences of the focal goal influences the desirability of the focal goal.

A related literature in decision making has focused on the emotions of regret and, to a lesser extent, disappointment (Zeelenberg et al., 2000). In an early study, Simonson (1992) showed that when consumers were reminded that they might later regret a bad decision, they were more likely to choose a higher-priced, brand-name product, presumably because this was expected to shield them from possible future regret. More recently, Mellers and her associates (e.g., Mellers & McGraw, 2001) developed a comprehensive framework for considering the effects of anticipated emotions on choice called subjective expected pleasure theory (see Heyman & Mellers, chapter 27, this volume).

Influence of Exogenous Affect on Goal Setting

Exogenous moods and emotions, which originate outside current goal pursuit, can have both direct and indirect effects on goal setting. With regard to direct effects, it has been known for quite some time that incidental positive mood (induced by a small gift, for example) tends to increase the likelihood of pro-social behaviors (see Cohen et al., chapter 11, this volume).

More recently, researchers have become interested in the effects of specific exogenous moods and emotions on behavior and goal pursuit. As a case in point, Raghunatham and Pham (1999) contrasted the effects of sadness and anxiety. They argue that since sadness is associated with appraisals of loss, sad individuals will be motivated to replace their loss with something else that is rewarding, leading to an implicit goal of reward acquisition. In contrast, fear is associated with appraisals of uncertainty and lack of control, which may prompt a goal of uncertainty reduction. Consistent with expectations, sad individuals had a greater preference for high-risk/high-reward options, whereas the opposite was true for anxious individuals.

Exogenous affect can also influence goal-directed behavior indirectly by impacting judgments of the desirability and feasibility of goals. A well-established finding in the mood literature is that moods tend to bias evaluations in mood-congruent directions (see Cohen et al., chapter 11, this volume). This suggests that a goal, or the outcomes and consequences associated with the goal, may be evaluated more positively when a person is in a good mood and more negatively when the person is in a bad mood. Exogenous mood can also influence estimates of the likelihood that particular events will occur, thus affecting feasibility. For example, Johnson and Tversky (1983) found that people who read happy newspaper articles provided more optimistic risk judgments than people who read sad articles. Recent research has qualified and extended these findings by arguing that judgments may be sensitive to the particular exogenous affect experienced. For example, Lerner and Keltner (2000, 2001) proposed the so-called appraisal-tendency hypothesis, according to which the appraisal dimensions that caused an emotion also influence people's evaluation of objects and events that are encountered while they experience the emotion in question. Lerner and Keltner apply their model to fear and anger, and reason that since fear is characterized by uncertainty and situational control, it should lead to higher risk perceptions, whereas anger should lead to lower risk perceptions since it is characterized by certainty and personal control. The authors find support for these predictions not only for dispositional fear and anger (measured with personality variables) but also experimentally manipulated exogenous sources of fear and anger. Such findings reflect what we call the *affect-as-filter* function in goal setting (see Table 13.1), where the perception of incoming information is biased toward the currently experienced affect and its appraisal dimensions.

Goal Setting Influence on Affect

So far we have examined how affect influences goal setting. However, the goals that people set may have affective implications (i.e., externalities) that are independent of the specific outcomes of goal pursuit. We call these influences *hedonic spillover* (see Table 13.1). We distinguish two types of spillover here. First, there is evidence that certain goal orientations (i.e., individual differences in how goals are represented mentally) have characteristic effects on subjective well-being such as life satisfaction and the frequency with which positive and negative affective states are experienced. Second, goal content seems to have important ramifications for well-being. Specifically, extrinsic goals such as those related to financial success and materialism have generally been linked with lower well-being.

The first goal orientation is abstractness or level of goal specification. This goal dimension refers to whether people tend to frame their goals in concrete or abstract ways. For the present purposes, it suffices that there appear to be reliable individual differences in the extent to which people identify their goals and behaviors in superordinate or subordinate terms (i.e., “level of personal agency” in action identification theory). For example, high-level agents may identify the act of eating as getting nutrition, whereas low-level agents might think of it as chewing and swallowing.

Emmons (1992) investigated the relationship between level of goal specification and psychological and physical well-being. He asked three different sets of participants to generate 15 personal strivings (i.e., goals that they were typically trying to attain) and had coders rate a person’s strivings as either relatively concrete, specific and more behavioral in nature, or as abstract, reflective, and involving greater self-scrutiny. Emmons also collected reports of daily moods, ratings of life satisfaction, and other measures of psychological well-being (e.g., depression, anxiety), as well as various indices of physical well-being (e.g., health center visits). Interestingly, high-level strivings tended to be associated with certain indicators of lower psychological well-being but fewer symptoms of physical illness. Emmons (1992) argues that it is more difficult to attain and monitor progress toward abstract goals, which leads to negative affect for high-level strivers. On the other hand, low-level strivers may be more prone to repress stressful experiences and as a consequence suffer physical illnesses.

Psychological and physical well-being have also been linked to another goal orientation, namely, whether people frame their goals as approach or avoidance goals. Approach goals are desired states that one wants to attain (e.g., spending time with others), whereas avoidance goals are aversive states that one wants to avoid (e.g., being lonely). Emmons and Kaiser (1996) coded the personal strivings elicited from four sets of respondents into approach and avoidance strivings and then correlated the proportion of avoidance strivings (which ranged from 9 to 15% overall) with measures of psychological and physical well-being (similar to those used in Emmons, 1992). People with a relatively high proportion of avoidance strivings tended to experience less positive affect, lower life satisfaction, and more anxiety. In addition, they reported more symptoms of physical illness. One reason for these differences might be that, compared to avoidance strivings, approach goals were rated as more desirable and important, success was seen as more likely, and goal pursuit was based more on intrinsic reasons.

A third goal orientation is goal conflict, which we introduced earlier. In Emmons’ work on personal strivings, ambivalence (approach-avoidance conflict) is assessed as the degree of unhappiness one would feel about succeeding at the striving, whereas goal incompatibility is measured as the extent to which success at one striving has helpful or harmful effects on another striving (averaged across all possible pairs of strivings). Both ambivalence and incompatibility have been

associated with lower psychological well-being and various physical symptoms, including more frequent health center visits (Emmons & King, 1988).

The final goal orientation is goal differentiation. Emmons and King (1989) define differentiation as the degree to which different goals (i.e., personal strivings in their study) are independent rather than interdependent. For example, one operationalization of this construct is the rated dissimilarity between a person's strivings. Emmons and King argue that striving differentiation should be associated with greater affective reactivity, and in two studies they find support for this hypothesis for both a measure of affective intensity (i.e., the intensity of experiencing positive and negative moods over a period of time) and affective variability.

The second approach to studying the relationship between goals and subjective well-being is based on the notion that well-being is not only a function of structural characteristics of goals, such as their level of differentiation, but also the content of goals. Of particular importance to consumer behavior is the finding that extrinsic goals such as financial success, social recognition, and appearance can have a detrimental effect on well-being (although the direction of causality is not always clear from the existing studies, the findings are usually interpreted in this way). For example, Kasser and Ryan (1993, 1996) established that people who assigned greater importance to aspirations such as self-acceptance (concern with growth, autonomy, and self-regard), affiliation, community feeling, and physical fitness, and thought they could attain these goals in the future, rated more highly on a variety of indices of well-being (including diary measures of experienced positive affect and depression and anxiety), whereas people who endorsed values relating to financial success, appearance and social recognition had lower well-being scores.

There is generally good support for a negative effect of materialism on well-being, but there also seem to be important boundary conditions. Burroughs and Rindfleisch (2002) propose that materialism will lead to stress and lower well-being when it conflicts with collective-oriented values. In two studies (a large-scale survey with a representative sample of American adults and an experiment with students) they find support for this notion for two of the three collective-oriented values studied, namely, religious and family values, although not for community values. The foregoing results show mostly negative affective implications of particular goals and goal setting situations, and more research about potential positive implications would be welcome.

AFFECT AND GOAL STRIVING

Affect has different functions in goal striving as well. First, affect experienced during goal striving provides information about goal progress, and directs and energizes future goal striving (endogenous affective influence). Second, affect that is unrelated to the process of goal pursuit can influence future goal striving (exogenous affective influence). Third, goal striving may be successful or unsuccessful, thus inducing positive or negative affective states as a function of the goal outcome (affective output). Table 13.1 (third column) summarizes these functions in our model. We focus on the first two functions because they exert an important influence on current goal pursuit, and also because affect-as-output has been documented in detail by emotion theorists in psychology and marketing (Bagozzi, Gopinath, & Nyer, 1999; Frijda, 1986; Gross, 1998).

Influence of Endogenous Affect on Goal Striving

Affect arises when goal progress is thwarted or facilitated. The cause and effect functions of such endogenous affect are closely intertwined because affect, on the one hand, provides feedback about current and past goal striving (*affect-as-feedback*) and, on the other, directs future goal striving

(*affect-as-volition*). But how does affect arise during goal striving, which types of affect are generated, and how does affect influence goal striving?

Theories of affect are often not very precise about how goal progress leads to affect (Frijda, 1986; Lazarus, 1991; Roseman, Antoniou, & Jose, 1996; Stein, Trabasso, & Liwag, 1993). One prominent exception is Carver and Scheier's control theory of affect (Carver, Lawrence, & Scheier, 1996). The theory argues that progress at a rate higher than some standard generates positive affect. This implies that somebody might be making progress toward a goal, but if the progress is slower than expected, the affect experienced could still be negative.

There are at least three possibilities about how goal progress or lack thereof can induce affect (Carver et al., 1996). For simplicity, we frame the three ways in terms of positive affect. First, the absolute rate of progress may elicit affect such that any movement toward (away from) an approach (avoidance) goal leads to positive affect. Second, the relative rate of progress may elicit affect: the faster one moves toward (away from) an approach (avoidance) goal, the more likely the experience of positive affect and the greater its intensity. Alternatively, the movement may be compared to an expected, acceptable, or desired rate of movement, and the nature and intensity of affect depends on the speed of movement relative to the chosen standard. Third, changes in the rate of progress may elicit affect such that if the movement toward (away from) an approach (avoidance) goal accelerates over time, positive affect will be generated. Hsee and Abelson (1991) and Hsee, Salovey, and Abelson (1994) have provided support for the affective implications of all three aspects of goal progress using satisfaction with various outcomes as the criterion. Boldero and Francis (2002) speculate that in the case of what they call standards (i.e., desired states in the present), the magnitude of the discrepancy with the standard matters, whereas with goals (i.e., desired states in the future) the rate of discrepancy reduction relative to an expected rate is critical for emotional experience.

Initially, the focus in goal theory was on the overall valence of the affective state, either positive or negative (Carver, Lawrence, & Scheier, 1996). More recently, specific affective states have been considered in detail. As a case in point, regulatory focus theory (Higgins, 1997) specifies that if people are doing well in their approach strivings (e.g., achievement goals), they will feel cheerful, excited, and elated, whereas when they are doing poorly they will feel dejected, sad, and depressed. In contrast, when people are doing well in their avoidance strivings (e.g., protection goals), they will feel quiescent, relieved, and calm, whereas when they are doing poorly they will feel agitated, anxious, and nervous (see also Carver, Sutton, & Scheier, 2000).

The affect-as-feedback function is essentially retrospective, whereas the affect-as-volition function is prospective. This is because the experience of specific affect does not only comprise thoughts and feelings but also so-called emotivational goals and action tendencies (Frijda, 1986; Roseman, Antoniou, & Jose, 1996). For example, the experience of regret activates a person to try to undo a behavior or its undesirable outcomes.

The affect-as-feedback and affect-as-volition functions in goal striving are integrated in the work of Stein (Stein, Liwag, & Wade, 1996; Stein, Trabasso, & Liwag, 1993) on the unfolding of emotional experiences over time. The theory proposes a limited number of goal-outcome-goal-revision combinations, each with a distinct corresponding emotion. A precipitating event that is seen as facilitating or obstructing a goal, along with an evaluation of certainty of goal success or goal failure, causes an emotion. Specifically, being certain about attaining something desirable or not attaining something undesirable leads to happiness; not attaining something desirable or experiencing something undesirable lead to sadness and anger; and not wanting an undesirable uncertain outcome or wanting a desirable uncertain outcome leads to fear. Depending on the emotion, a goal to attain, maintain, reinstate or avoid is generated, or the goal is substituted or abandoned. If no plan is available, the original goal is forfeited or it is replaced with a new goal if this

course is acceptable (which is often the case in sadness), otherwise the person redoubles efforts to find a plan. If a plan is available, it is enacted in an effort to reinstate the original goal (e.g., in anger attempts are usually made to remove the goal blockage) or to prevent an undesirable state (e.g., in the case of fear). Subsequently, the outcome is monitored, and a new goal-outcome-goal-revision cycle is initiated.

In line with this, Bougie, Pieters, and Zeelenberg (2003) found that consumers who were angry due to a service provider's wrong-doing experienced emotivational goals such as trying to get back at someone and wanting to hurt someone, and action tendencies such as feeling like behaving aggressively and feeling like letting oneself go. They also found that, independent of the level of dissatisfaction with the service, higher levels of anger increased the likelihood that consumers would complain to the service provider, which reflects attempts to attain the original goal of the service encounter, rather than abandoning it.

A related framework is the communicative theory of emotions (Oatley & Johnson-Laird, 1996), which is also based on the idea that emotions are caused by perceived changes in the likely success of plans. Emotions alert people to those parts of the goal structure that require attention and lead to evaluations of what can be done about the situation. For example, the theory suggests that the behavioral consequences of happiness are to continue with the plan; of sadness to disengage from the goal; of fear to stop, attend to the environment, or escape; and of anger to try harder or aggress.

Bagozzi, Baumgartner, and Pieters' (1998) research on goal-directed emotions is also relevant to goal striving. They assume that people can anticipate how they would feel if they achieved their goal and how they would feel if they failed to achieve their goals. These anticipated emotions initiate volitional processes in which intentions and plans about how to enact the chosen goal are formed and decisions about effort expenditure are made. Instrumental behaviors aimed at goal attainment are then executed, goal attainment is evaluated, and goal-outcome emotions are experienced. Bagozzi et al. tested these ideas in a longitudinal study of weight control, using data from 406 adults who already had a weight loss or weight maintenance goal. The findings showed that positive and negative anticipated emotions influenced both dieting and exercising volitions, which in turn impacted dieting and exercising behaviors. For men, perceived goal attainment was a function of exercising, whereas for women it was a function of dieting. Furthermore, greater goal attainment led to more positive and less negative goal-outcome emotions.

Finally, decision-making research on the behavioral effects of currently experienced specific emotions such as regret and disappointment has implications for goal striving. For example, Zeelenberg et al. (2000) argue that experienced regret leads to a focus on nonattained goals and encourages persistence in goal pursuit, whereas disappointment promotes goal abandonment. In a services context, Zeelenberg and Pieters (1999) showed that regret had a direct effect (unmediated by dissatisfaction) on switching, whereas disappointment had a direct effect (unmediated by dissatisfaction) on negative word-of-mouth.

Influence of Exogenous Affect on Goal Striving

During goal striving, consumer may experience affect that is unrelated to goal pursuit, which may nonetheless influence goal pursuit. As suggested by Seo, Feldman, Barrett, and Bartunek (2004), who discuss the role of affective experience in work settings, such exogenous affect can influence the amount of effort expended on goal pursuit as well as the persistence of goal striving directly or indirectly through judgments of goal progress (*affect-as-volition*). With regard to direct effects, they propose that activated affective states may result in greater effort expenditure and that pro-

cesses of mood maintenance and mood repair may encourage the continuation of a current activity or lead to a change in plans. With regard to indirect effects, they rely on research which shows that good (bad) mood induces more heuristic (systematic) processing of information to argue that people in a good (bad) mood will monitor progress toward a goal less (more) frequently, less (more) thoroughly, and more (less) favorably.

Martin (e.g., Martin et al., 1993; Martin et al., 1997) argues that the valence of a person's mood by itself does not have clear motivational implications. Rather, moods have to be interpreted and depending on the meaning ascribed to one's mood, a given mood may have very different motivational effects (*affect-as-input*). For example, in Martin et al. (1993) the effect of "stop rules" on behavior was investigated, that is, when to terminate goal pursuit. Participants engaged in a task with instructions that encouraged them to stop when they had reached their goal (goal attainment) or to stop when they no longer enjoyed the task (task enjoyment). Thus, the goal attainment instruction induced an (external) outcome or performance goal, whereas the task enjoyment instruction promoted an (internal) process or learning goal (Dweck & Leggett, 1988). With goal attainment instructions, participants in the positive exogenous mood condition stopped earlier than participants in the negative exogenous mood condition, presumably because a positive mood implies doing well on a task or at least making progress toward the goal. The opposite was true with the task enjoyment instructions, because in this case a positive mood should promote maintenance of the behavior.

Although it does not deal directly with goal striving, the work of Bosmans and Baumgartner (2005) on goal-relevant emotional information is relevant here as well. These authors induced different exogenous emotions in participants and exposed them to ads that appealed either to achievement or protection motives. When the ad made achievement goals salient (e.g., increasing one's energy by eating organically grown apples), participants evaluated the product (i.e., the brand of apples) more favorably when participants happened to feel cheerful rather than dejected, but there was no difference in brand evaluations for participants who felt quiescent versus agitated. In contrast, when the ad made protection goals salient (e.g., preventing fatigue by eating organically grown apples), participants who felt quiescent provided higher brand evaluations than participants who felt agitated; there was not difference between participants who felt cheerful or dejected.

CONCLUDING THOUGHTS

Based on a review of the literature, this chapter developed a framework describing the interplay of goals, action, and affect in goal-directed consumer behavior. The framework is based on the idea that goals are organized in hierarchical structures, and that goals derive their meaning from relationships with goals at the same level of the hierarchy and goals lower and higher in the hierarchy. Based on the notion of goal hierarchies, we indicated the relevance of the abstractness or specification level of goals, and noted that consumers can flexibly adapt their level of goal identification (i.e., what they are pursuing) depending on the demands and novelty of the task, the distance to goal implementation, and individual differences. Next, we described goal setting and goal striving as separate but related processes in consumers' goal pursuit, and discussed the role played by affect in goal pursuit. Our framework assumes that in most circumstances affect serves goal-directed consumer behavior in multiple ways. Specifically, affect was shown to function as a goal, filter, feedback, and source of motivation and volition, among others. With regard to goal setting, some goals are affective in nature, in which case affect is an intrinsic motivator (*affect-as-goal*), whereas other goals derive motivational potential from anticipatory and anticipated affective reactions associated with goal achievement (*affect-as-motivation*). Affect unrelated to goal setting may also color

consumers' perception of goal-relevant information (affect-as-filter), and affect can result as a function of the types of goals consumers set (affect-as-hedonic spillover). With regard to goal striving, affect provides feedback about goal progress (affect-as-feedback) and the affect generated in turn directs future behavior (affect-as-volition). In the control loops that occur during goal pursuit these various functions of endogenous affect are intertwined, and more research is needed to understand when and how these antecedent and consequent functions of affect promote successful goal pursuit. In addition, exogenous affect emanating from outside the specific goal pursuit may influence goal striving as in affect-as-input. Finally, after all is said and done, and goal pursuit has been successful or unsuccessful, affect serves as hedonic output. Then, consumers are happy with their flat tummy, relieved to be without debt, proud to have bought the best computer for less, and so forth.

As always, further research is needed and we have raised possible avenues at various places in the chapter. As mentioned at the beginning of the chapter, it is surprising that consumer researchers have paid so little attention to goal-directed consumer behavior because much of what consumers do involves goal pursuit, not only when they are trying to keep to their diet, but also when they are saving money, trying to stay out of debt, planning their holidays, raising their kids without buying them too much or too little, and so forth. Amazingly, we know very little about such patterns of behavior over time, where consumers try to attain or maintain long-term and abstract goals, and what functions affect has in goal pursuit. And we know even less about how consumers deal with multiple goals over time, without breaking down. Researchers have generally emphasized breakdowns of control, such as when people overeat, drink too much, or consume compulsively, but one should probably be more amazed by the fact that most consumers do a fairly good job at juggling a multitude of goals at the same time. It would be interesting to find out how they accomplish this.

Goal-Directed Perception

CHRIS JANISZEWSKI

University of Florida

The study of perception is guided by metaphors of the mind and the role perception plays within the context of the metaphor. For example, consider the metaphor that the mind is a machine or that the mind operates like a computer program. In this metaphor, perception is an act that allows the system to represent the environment as a series of symbolic concepts that can be input into higher order processes (i.e., it is a decoder). Consistent with the computer program metaphor, an identical input should be perceived in a constant fashion (1) by the same person on different occasions or (2) by different people on the same occasion. The assumption of *perceptual invariance* allows researchers to make inferences about higher order processes that manipulate these perceptual inputs, without worrying about the variability of the inputs. The computer metaphor also directs the research of those that focus on the act of perception. If cognition depends on software, then the goal of perceptual research should be to discover fundamental subroutines (i.e., decipher the programming code). Research on feature identification, feature integration, and visual search all seek to discover how a perception is constructed.

An alternative metaphor of the mind is the neural metaphor. In this metaphor, the mind is composed of neurons that must learn to execute motor and, subsequently, conceptual acts. To execute any one simple act, a considerable amount of parallel processing and coordination must occur. In this metaphor, perception is the act of isolating and assigning meaning to the neural activation that was responsible for the execution of motor and conceptual acts. As the individual develops a larger array of motor and cognitive abilities, perceptual processes are used to (1) identify patterns of neural stimulation that are useful for goal achievement and (2) identify the differentiating characteristics of neural activation that lead to unexpected, but relevant outcomes. In this type of model, systems for initiating motor acts, representing sequences of neural activation, and assigning the cognitive concepts to these sequences, are all related through their overlapping neural activation. If perception is a consequence of the selection of a neural array, then the goal of perceptual research should be to discover how meaning is created at any given moment, how meaning motivates behavior, and how verbal, motor, and affective responses interact owing to their common source of initiation (i.e., perception).

The goal of this chapter is to provide insight into the content and consequences of perception (the neural metaphor) as opposed to the processes used to generate or use a perception (the computer metaphor). The review begins with a historical account of the many metaphors that have been used to account for perceptual processes. This review is meant to illustrate two points. First, privileged metaphors are inevitably replaced when they are no longer able to offer any additional insights. Second, there are recurrent themes that permeate the history of perceptual research. The

review continues with a discussion of two recent accounts of perception, proposed by Anthony Marcel and Michael Tomasello, that are consistent with the neural metaphor. These accounts of perception are used as a foundation for a model of goal directed perception. The model is used to provide insight into a number of intriguing findings within the perceptual, cognitive, social, and consumer literatures.

HISTORY OF PERCEPTUAL THEORY

Early Perceptual Research

The study of perception has been an ongoing topic of inquiry for over 2,000 years. Many of the early theories of vision and perception incorporated emission (i.e., light emitted by eyes), reception (i.e., light reflected by objects and received by eyes), or a combination of the two (see Wade 2001 for discussion). Democritus (460–370 B.C.) hypothesized that objects emit moving atoms that displace air and leave an imprint on the eye. Plato (427–347 B.C.) proposed that both the object and the eyes emit light and that vision occurs when the two streams of light intersect in space. Aristotle (384–322 B.C.) rejected the emission assumption, owing to the inability of people to see in the dark, and argued that objects reflect light that displace the medium (e.g., air) between the object and the viewer. Euclid (365–275 B.C.) proposed that the eyes emit visual rays at varying densities within the visual field. Euclid used his approach to deduce important principles in visual acuity, foveal and parafoveal vision, and spatial perception. Ptolemy (85–165 A.D.) advanced Euclid's ideas by arguing that both eyes emitted continuous light rays and that the differences in object displacement for each eye were the source of depth perception. Kepler (1571–1631) was the first to discuss a reception theory that incorporated the optics of the eye, arguing that the retina acted like a camera obscura and that vision was the recording of an image.

The 17th Through 19th Centuries

Perceptual research in the 17th through 19th centuries represents an initial appreciation for the perceptual content versus perceptual process distinction. Rationalists, including Descartes (1595–1650), Spinoza (1632–1677), and Leibniz (1646–1716) argued that meaning was derived through reasoning, logic, and mathematical principles. The goal of perceptual research should be an understanding of these processes (i.e., the innate laws of perception). Empiricists,¹ including Locke (1632–1704), Berkeley (1685–1783), and Hume (1711–1776), argued the laws and knowledge used to assign meaning were initiated, refined, and generalized through experience (i.e., perception, and by extension knowledge, is subjective). Locke solved the subjective content problem by arguing that the study of perception should be limited to the objective qualities of objects (e.g., shape, size, quantity, and movement), forsaking the more subjective qualities (e.g., color, taste, and temperature). Berkeley adopted the more radical position that all perceptual experience is subjective and that there was no way to have true knowledge about the state of the world, and by extension, the laws of perception.

The work of Weber (1795–1878) and Fechner (1801–1887) was a direct response to the claim that the discipline of psychology could not be scientific owing to the subjective nature of perception (Ballantyne, 2003). Weber showed that the just noticeable difference in stimulus intensity (i.e., touch sensation) was proportionate to the current intensity of the stimulus and that the proportion was constant across levels of stimulus intensity ($k = \Delta I / I$). Weber further found that just noticeable differences varied by the location of the receptors (e.g., tongue, arm, back) and that active discrimination (i.e., lifting weights) is more sensitive than passive discrimination (i.e., holding weights).

Fechner described the empirical laws of subjective perception in mathematical terms (e.g., Sensation = $K \log R$; where R = stimulus value), setting the foundation for modern psychophysics. By demonstrating that subjective perception behaved in a systematic and predictable way (i.e., focusing on process), Fechner countered Berkeley's claim that the study of perception was inherently nonscientific.

Helmholtz (1821–1894) took an alternative approach to Berkeley's criticism and theorized about the source of perceptual content. For example, Helmholtz adopted a reductionist position and proposed that sensations from external stimuli (elemental units) were impoverished. To achieve meaning, these sensations were combined with learned unconscious associations. Helmholtz argued that perception did not have to be an accurate representation of the sensory data because the unconscious associations encouraged the most likely representation (i.e., the likelihood principle). In effect, the perceiver was a problem solver that used subsets of the sensory data to generate hypotheses and then selected the hypothesis that had the best goodness of fit with the data. These hypotheses were learned, confirmed, and updated with experience (i.e., empiricism assumption). Helmholtz's approach was especially appealing because it offered a solution to the vexing problem of object constancy—i.e., the fact that perception is not sensitive to changes in the size, brightness, and shape of the retinal image that occur when an object is manipulated in space and/or the viewer moves in space. In summary, Helmholtz was the first prominent researcher to theorize about the contents of perception.

The remainder of the 19th century perception research focused on what were, and were not, appropriate areas of psychological study. Wundt (1832–1920) argued that there was a set of basic processes (e.g., sensation, perception, reaction time) that were observable through a scientific method and a set of higher order processes (e.g., meaning, memory, language, intention) that could not be observed owing to the reactivity inherent in self-reports (i.e., the subjectivity of perception). The defining feature of basic processes was that they were simple and could be evoked by external stimuli, hence responses to changes in the characteristics of these external stimuli could be mapped. Yet, Wundt did not see perceptual processes as elemental, arguing that a series of tones could make a chord and that perception of each tone was not necessary to appreciate the chord. This holistic perceptual process, called creative synthesis, was also supported by the finding that reaction times to letters and words were equivalent and that the number of flashed letters or words people can remember averages four to six units. In contrast, Titchener (1867–1927) adopted a more reductive position than Helmholtz and argued that all cognition was elemental. Perceptions were created by combining sensory elements and higher order processes were combinations of these perceptions. Külpe (1862–1915) offered a third view, arguing that higher order processes were a relevant topic of inquiry and that there were meaningful and persistent relationships between task instructions and behavioral responses. Thus, Külpe adopted a much more molar level of analysis, assuming perceptions were inputs into higher order processes, but not worrying about their source.

Direct Perception

James J. Gibson and Eleanor J. Gibson (E. J. Gibson, 1969; J. J. Gibson, 1966, 1979) made the next significant contribution in the conceptualization of the contents of perception.² Prior to the Gibsons' critique, it was assumed that the role of the visual system, and the sensory system in general, was to gather information for subsequent interpretation. The visual sensory system was passive, recording stimulation, in a manner similar to a video camera.³ The Gibsons' insight was that the sensory system is part of an active system that must accomplish goals by navigating the environment. If this is so, the unit of analysis should not be the retinal image of an isolated object, but the

array of ambient light reflected in a dynamically changing environment. The study of perception should not focus on the construction of meaning from the integration of elemental units, but the differentiation of events within the overly rich environment so as to make them useful during current and future goal pursuit. In effect, the Gibsons' reversed the Helmholtzian perspective, arguing that the environment was too rich, not too impoverished, to be useful without additional processing. In an overly rich environment, a person cannot possibly perceive each individual element and then integrate the elements, so it must be the case that people discriminate patterns among the stimulation.⁴

J. J. Gibson viewed visual perception as the act of identifying structure in the light reflected by an environment (i.e., a perception is selected, not constructed). Gibson observed that light reflects off surfaces in a lawful manner. Therefore, each point of ambient light within the visual array provides information about the reflecting surfaces facing that point. Through experience, a person learns to interpret the relationships among the points of light (i.e., assign meaning to the structure in the array). This ability to isolate structure in the visual array of light is useful when combining information from each eye or when attempting to maintain object constancy. The person also learns how to combine this information about ambient light with kinetic information, so that the perceptual representation is of the perceiver in the environment (i.e., one could not catch a ball if the ball and the hand could not be represented in perceptual space). Repeated sampling of the environment, and sensitivity to invariants (e.g., ambient light related to contours and texture), allows the perceiver to perceive certain items as stationary and others as moving within the environment, even when the perceiver is moving. Gibson also argued that perception is defined by the organism's goals in its current environment. Representation consists of the acts that can be performed with an object, "what it provides or furnishes, either for good or ill" (Gibson, 1979). This insight explains the diversity of visual systems among species and the variance of perceptual responses to common environments among different people and cultures.

Present Day Perceptual Research

The historical review of perceptual research is meant to illustrate that both content and process have been important topics in the investigation into the act of perception. Yet, if one were to review the past 50 years of perceptual research, a large majority of the effort has focused on process, as opposed to content. Major process contributions include feature detection theory (Julesz, 1971), feature integration theory (Treisman & Gelade, 1980), pattern matching (cf. Geisler & Super, 2000), object perception (cf. Kersten, Mamassian, & Yuille 2004), visual search behavior (Posner, 1980; but see Vecera & Farah, 1994), and enumeration (cf. Trick & Pylyshyn, 1994). This conclusion extends to consumer research. A large majority of consumer researchers assume perception is a process that generates an output to be used in higher order information processes (Greenwald & Leavitt, 1984). The primary exceptions to this conclusion are research on semiotics (e.g., McQuarrie & Mick, 2003; Mick & Buhl, 1992), literary criticism (e.g., Stern, 1993), and volume, size, and distance perception (e.g., Brooks, Kaufmann, & Lichtenstein, 2004; Raghurib & Krishna, 1996, 1999).

In the next section, I discuss two relatively modern theories of perceptual content. Anthony Marcel exemplifies the elemental, constructive, mediated approach to perception first proposed by Helmholtz. Michael Tomasello exemplifies and the selective, differentiating, direct approach to perception first proposed by the Gibsons. These theories are interesting because they differ considerably in orientation, but attempt to address the perceptual variance problem that has plagued perception research since its inception. Perceptual variance refers to the idea that the same stimulus can have different meanings in different contexts. Marcel emphasizes perceptual experience and

attempts to explain *how* a perception is generated. Tomasello emphasizes goal-directed behavior and attempts to explain *why* a perception is generated.

THE VARIANCE OF PERCEPTUAL CONTENT

Anthony Marcel

Anthony Marcel's (1983b) theory of perception addresses the issue of perceptual variance by advocating a role for the subconscious in perception. Marcel defines his theory by challenging the assumptions common to mainstream perceptual research. First, Marcel rejects the assumption that cognition and conscious experience are one in the same (i.e., the Identity Assumption). Second, Marcel rejects the assumption that behavior can only be directed by the contents of conscious experience (i.e., Directed Thought Assumption). Third, Marcel rejects the assumption that external stimuli engage the perceptual system as a series of discrete events (i.e., Discrete Sampling Assumption). Of these assumptions, the first two directly address the issue of perceptual variance. By allowing for cognition and conscious experience to be dissociated, Marcel allows for perceptual invariance at the subconscious level, but perceptual variance at the conscious level. In this way, subconscious perception can direct behavior, whereas conscious experience can only provide an account of the behavior.

Marcel (1983a) provides an interesting empirical demonstration to support his position. Marcel presented masked stimuli for very short periods of time and asked viewers to indicate (1) whether or not they saw a stimulus (presence/absence judgment), (2) which of a pair of stimuli had more graphic similarity to the presented stimulus (graphemic similarity), and (3) which of a pair of stimuli had more semantic similarity to the presented stimulus (semantic similarity). Although one might expect that reduced presentation times will impact semantic judgments prior to graphemic judgments prior to presence/absence judgments, the opposite pattern of results was observed. That is, for a given presentation duration, people were quite accurate (e.g., over 90%) at making semantic judgments even though they were fairly inaccurate (e.g., 55%) at making presence/absence judgments. The implication is that the subconscious can respond to the environment before conscious, subjective experience has an opportunity to exist. Marcel argued that this demonstration was inconsistent with the identity and directed thought assumptions because conscious thought did not direct responses in the semantic similarity judgments. Marcel further argued that any of a number of conscious experiences could be produced from the same array of subconscious activation.

Marcel was not the first to claim a dissociation between the "sources of behavior" and conscious thought (e.g., Freud, 1856–1939; the behaviorist movement in the first half of the 20th century), even within the standard information processing paradigm (e.g., Nisbett & Wilson, 1977). Yet, Marcel was one of the first to describe a perceptual processing system in which the determinants of behavior were independent of conscious experience. Marcel proposed that subconscious perception depended on distributed processing in that all sensory stimulation is analyzed, transformed, and redescribed into all possible forms of representation automatically and independently of consciousness (all perceptual variants exist in the subconscious). These moment-to-moment representations are both temporary (called a *result*) and sustained (called a *record*). Results are subconscious perceptions that can be used as input into other processes, to direct behavior, to prime related concepts, and to suggest candidate hypotheses for conscious experience. Because conscious experience is a slow process, these candidate hypotheses are then fit to records, the more permanent trace of the moment-to-moment representations. Thus, Marcel believes conscious experience is a behavior produced by the subconscious that does not have special status relative to other behaviors (e.g., motor responses, affective responses, language) produced by the subconscious.

Perceptual variance occurs because of the way in which conscious percepts are fit to records. Marcel argues that the constructive act of generating a conscious experience depends on expectancy, frequency, and a tendency to have experiences corresponding to the highest or most functional level of representation. This means that the selection of a conscious experience is sensitive to recent experiences and the constraints of the current processing goal (i.e., consciousness is context specific). The perception of an object is variable because the object is encountered in different contexts. These contexts can be prior thoughts, the environment, or task objectives.

Critique. Marcel's theory represents a departure from traditional perceptual theories because it minimizes the role of conscious experiences in directing behavior. The strength of Marcel's theory is that it provides a detailed account of how a person can use the subconscious to respond to the environment, from mundane postural adjustments to more meaningful choice behavior. Marcel's theory also provides insight as to why conscious experience is variable and why this variance need not limit research into cognition. The weaknesses of Marcel's theory is it (1) does not specify how subconscious records come to motivate behavior, (2) why any one record should be more influential than another, (3) how goals are integrated into the perception/behavior system, (4) how people generate creative behavior and thought, and (5) why consciousness exists and/or when it might exert an influence on behavior.

Michael Tomasello

Michael Tomasello (1999) adopts a cultural, evolutionary perspective on perceptual development, thus addressing the issue of perceptual variance from a functional perspective. Tomasello argues that perceptual processes cannot be understood unless one understands the role these processes play in development (i.e., why they exist). Tomasello remarks that human infants are born without the ability to survive. In order to survive, infants must learn how to achieve goals through the efforts of others. Owing to their dependence on others, infants develop a communication system, both verbal and nonverbal. In effect, children and caregivers develop a communication system that allows each of them to understand the needs of the child. Perception supports the communication system and, ultimately, must support goal identification and achievement.

Tomasello (1999) contends that the human communication system is unique among all species because humans have a special capacity to understand that their behavior, and *the behavior of others*, is intentional. Humans do not mentally represent others' behaviors as static outcomes. Humans represent the intent of others behaviors (e.g., a "moving person" can be running, chasing, or fleeing). Likewise, humans do not represent objects, but the intent associated with the use of the objects (e.g., a block of wood can be a paperweight, building material, or a weapon). Thus, perceptual processes operate in a system that is trying to understand why others behave as they do, help identify and represent the causes of these behaviors, and, as the individual develops, do the same with respect to achieving goals in a multitude of environments.

One of the critical assumptions of Tomasello's theory is that humans can take the attentional perspective of others. This ability is useful at all stages of development. For infants, behavioral modeling requires that the child understand the parent is trying to demonstrate a skill that helps achieve a goal. For example, by the age of 9 months, a child can be selective in its mimicry because it understands that only a subset of the observed behavior is necessary for goal achievement. This subset of behaviors must be differentiated relative to the host of available behaviors. This differentiation is a perceptual process. Likewise, language can be used to represent causes and effects associated with goal achievement. Between the ages of 18 and 24 months, the child becomes sensitive to the parent's use of common and novel communication symbols and can assign novel language

symbols to novel objects. This creation of a communication system is also a perceptual process. Novel language symbols are also assigned to novel objects used in intentional acts, but not to novel objects used in unintentional acts. This implies that language (and all its labels) exists because it allows a person to represent and communicate about intentional behavior.

Tomasello's theory incorporates many of the ideas advanced by the Gibsons, but adds insight as to the motivation for development of perceptual skills and the growth of a representational system. Perception is a dynamic and selective act, as opposed to static process, that relies on successes and failures in goal-directed behavior to determine what is worthy of representation and what is not. People use the environment, in combination with their personal perspective and/or the perspectives of others, to generate meanings associated with objects that are used in intentional behavior. These objects can be gestures, physical objects, symbols (e.g., words), or concepts. In this perspective, memory supports the creation of novel representations because it allows a person to note differences between prior and current activation.

Tomasello's theory of perception has three important implications. First, knowledge and meaning are goal-based. The meanings people assign to words, objects, behaviors, and situations are a consequence of the "uses" of these stimuli. Second, perception is perspectival in that the experienced meaning depends on a shared perspective. The same object, word, or gesture can have very different meanings depending on assumptions about the intent of the communicator. It is only in the absence of contextual information that signals intent that an object, word, or gesture will be represented consistent with its most common intent (i.e., the likelihood principle). Third, perception and behavior are symbiotic in their representation. If the purpose of perception is to understand intent, and meaning is intentional, then it should not be surprising that any ongoing behavior can influence perception (e.g., smiling while perceiving an event can influence perception of the event) or that perception can initiate behavior (e.g., mimicry).

GOAL-DIRECTED PERCEPTION

The work of Marcel and Tomasello represent the contrast in a Helmholtzian and a Gibsonian approach to perception. Despite this difference in approaches, each theorist addresses the issue of perceptual variance in an insightful way that, surprisingly, does not contradict the view of the other. Marcel accounts for perceptual variance by arguing subconscious perception is invariant, but that many possible conscious experiences can be assigned to representations available at the subconscious level. Tomasello accounts for perceptual variance by arguing that an item is assigned meaning according to the person's goals, prior experiences, and the item's function in the environment. The views of Marcel and Tomasello can be combined to create a hybrid model of perception that is consistent with the goal-directed view of Tomasello, but borrows some of the subconscious processing ideas advanced by Marcel.

First, let's begin with the assumption that perception depends on a distributed memory system (Fiedler, 2000; McClelland & Rumelhart, 1985). In this system, *concepts* are represented as a distribution of binary units that can be thought of as *feature codes*, as illustrated in Figure 14.1.⁵ For example, a dog has four legs, fur, a bark, a gait, etc., that can thought of as feature codes. The array of feature codes that define a concept can come from any combination of sensory systems (e.g., visual, aural, motor, proprioceptive) and need no have a corresponding verbal label. Concepts are created through a process of discrimination learning (i.e., each new concept includes the distribution of an old concept plus / less additional differentiating units). New concepts develop because previous concepts are insufficiently predictive, hence differentiating a concept is adaptively valuable. The act of perception is the act of selecting an existing concept(s) as pertinent to an ongoing

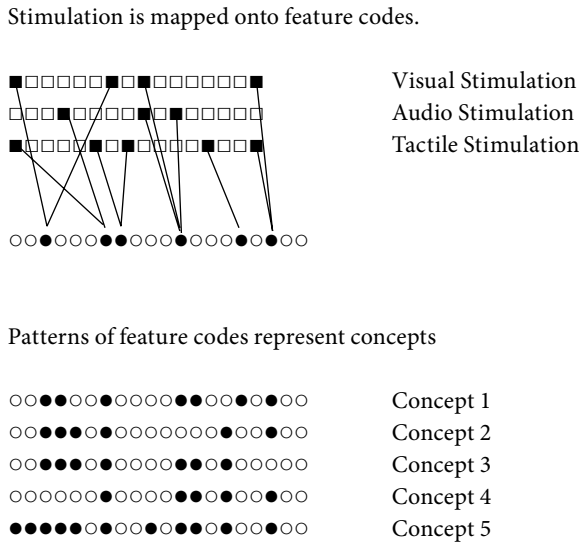

Figure 14.1 Illustration of distributed memory (adapted from Fiedler, 2000)

set of goals. Concepts can be communicative, emotional, or behavioral. More than one concept can be selected concurrently (i.e., a person can be talking while engaging in behavior). Meaning is inherent in all concepts, hence there is no need to propose a underlying semantic-concept system, although it may be easier to think in these terms.

The process of perception is noisy and imprecise for a number of reasons, including (1) there is a large amount of neural activation available at any one moment, owing to the complexity of the environment and the continuous nature of this activation; (2) an array of neural activation can support many concepts; (3) it is uncommon that any one concept will be uniquely represented in the array of neural activation (i.e., competing concepts can be activated by different subsets of the stimulation); (4) the selection of one concept can inhibit the simultaneous selection of other concepts that are based in the same response system; (5) the selection of a concept can prime the selection of related concepts in subsequent perceptions, and (6) inhibited concepts are less likely to be selected in subsequent perceptions. The process of perception is complex because multiple concepts (e.g., those supporting motor responses, emotional experiences, language) can be generated from the same pattern of neural activation. The process is also complex because the sensory system “observes” ongoing behavior (i.e., a person observes his behavior), hence overt responses become part of the array of neural activation for future perception (Welch, 1986).

The second assumption is that perception is goal-based (Allport, 1987; Hommel, Müsseler, Aschersleben, & Prinz, 2001). The term “goal” is used broadly in that the cognitive system is designed to allow the individual to accomplish acts. Thus, a pattern of neural activation can activate goals (i.e., one type of concept) and these goals can encourage the selection of concepts that are consistent with the achievement of the goal. Goals are represented as distributions of feature codes and these feature codes are part of many of the concepts represented in memory. Hence, overlap in the activation of the feature codes that define a goal concept and the feature codes that define other concepts can guide perception (i.e., the selection of communicative, emotional, or behavioral concept). In other words, once a goal becomes active owing to its perception, people become more likely to select concepts (i.e., generate perceptions) that include the neural activation that supported

the generation of the goal. The Theory of Event Coding (Hommel, Müsseler, Aschersleben, & Prinz, 2001) provides a detailed analysis of how distributions of feature codes come to have meaning and how the activation associated with a goal can encourage the selection of specific feature codes (e.g., features) for integration into a more complete concept. In effect, this allows for a hierarchical structure in the perception of concepts that support perception, although it does not imply that concepts are learned hierarchically.

The third assumption is that language/conscious experience is a type of concept in the perceptual system, but it is not *the* concept that guides behavior (i.e., conscious experience is not causal cognition). Still, conscious thought, language production, and motor acts are observed by the sensory system and are a source of subsequent neural activation. Hence, the cognitive system has the interesting property of being able to generate a conscious commentary that does not guide current behavior, yet being able to incorporate this conscious commentary into the concepts that guide future behavior.

Given these assumptions, I propose that perception has the following properties.

1. *Nonconscious*. Perception is an inherently nonconscious process. People may have concepts that support conscious experience, but this conscious experience is not the cognition that directs behavior.
2. *Act-based representation*. Object /environments acquire meaning from the acts they afford. People learn neural/cognitive representations (concepts) because they are useful in achieving goals. There is no incentive to parse the world into concepts other than those that help achieve (avoid) beneficial (harmful) outcomes. Meaning is an inherent property of any concept (i.e., the concept exists because it is useful), but there is no semantic network that is a fundamental basis for all concepts.
3. *Goal-directed*. People generate perceptions to help accomplish current goals. People only perceive the events in the environment that are instrumental to an ongoing task, failing to perceive that which is currently irrelevant. It is only in those instances where there are few active goals that people perceive events as the events have been commonly perceived in the past (i.e., rely on the likelihood principle) when selecting a concept. In other words, the recency and frequency of prior perceptual experience represents a default for current perceptual experience, but is often overridden by the perceptions necessary to accomplish currently active goals.
4. *Perceptual variance*. The same “stimulus” can afford a variety of concepts. The number and variety of concepts is influenced by the ambiguity of the environment and recently available concepts. As such, there can be multiple ways to perceive a stimulus (perceptual variance) and multiple actions initiated by the stimulus (i.e., automatic goal activation of multiple goals).
5. *Perception-act equivalence*. The perception of an act and the production of an act rely on common subset of neural activation or feature codes (cf. Hommel, Müsseler, Aschersleben, & Prinz, 2001; Kohler et al., 2002). The implication is that the act of perception can prepare the individual for behavior.
6. *Multi-process*. Perceptual learning implies both the creation of meaning and the assignment of meaning. The goal of the perceptual system is to differentiate the environment so as to become more effective at achieving goals. An adaptive perceptual system is always prepared to engage in the process of discrimination. The ability to discriminate depends on the ability to know what is old (i.e., a concept) and to create something new (i.e., isolate

a novel set of feature codes as a new concept). Thus, new concepts are defined because they are useful.

7. *Resource dependent learning.* People must differentiate the patterns and sequences of feature codes/concepts that lead to novel consequences in order to enable perception of these events in the future. In discrimination learning, a person must isolate the new pattern and receive feedback, directly or indirectly, on whether this differentiation is useful. Attention is necessary for the execution of the discrimination learning (i.e., attention is necessary to differentiate the new from the old). In humans, the isolation of the novel set of feature codes is accompanied by an experience of novelty and, for noninfants, a cognitive representation. The acts of discrimination, cognitive representation, and association formation between communication, emotion, and behavioral concepts contribute to the creation of meaning for the novel event.

The usefulness of the goal-directed view of perception depends on the ability of the perspective to account for findings that are not easily explained by more traditional models of perception. Below, I discuss a range of interesting and unusual findings and an effort to show the explanatory power of the goal-directed view of perception. The discussion will focus on demonstrations that (1) people exhibit perceptual “blindness,” (2) people initiate behavior nonconsciously, and (3) the conscious consideration of behavior alters behavior.

Perceptual Blindness

Inattentional Blindness. Simons and Chabris (1999) provide a popular demonstration that people can fail to perceive obvious events in their environment.⁶ Simons and Chabris ask participants to view a 75-second video of two three-player teams tossing basketballs. The participant’s goal is to keep separate counts of the number of bounce and aerial passes by the team wearing white (black) shirts, ignoring passes by the team wearing black (white) shirts. Forty-five seconds into the video, a woman in a gorilla suit or a woman holding an umbrella walks through the group of ball players. Afterwards, only 54% of the participants report having seen the gorilla and only 70% of the participants report seeing the woman with the umbrella. When the counting task is made easier (i.e., count the total number of passes), perception of the gorilla increases to 62% and perception of the woman with umbrella increases to 79%.⁷

Simons and Chabris’ demonstration is a compelling example of a phenomenon Mack and Rock (1998) call inattentional blindness. Mack and Rock report a large number of studies that use a common experimental procedure. Participants watch presentations of a cross on a screen and judge which of the two arms is longer. During the fourth trial, a secondary object (e.g., brightly colored rectangle) appears on the screen. When the cross is in the foveal visual field and the secondary object is in the parafoveal visual field, approximately 25% of the participants fail to notice the secondary object. When the secondary object is in the foveal visual field and the cross is in the parafoveal visual field (i.e., the cross changes locations relative to earlier trials), approximately 75% of the participants fail to notice the secondary object. Yet, when participants are informed that another object might appear, or are directly informed to watch for a secondary object, it is always noticed. The secondary object is also noticed when it is relevant to the individual (e.g., their name, a smiley face), but features that are thought to be preattentively hardwired to create attention (e.g., contrasting color, contrasting orientation) do not increase the likelihood of seeing the secondary object. For example, when the distracter item was a red circle in a field of green circles, only 33% of the participants saw the secondary object.

Demonstrations of perceptual inattention are consistent with the claim that perception is goal-directed. People fail to perceive events that are irrelevant to their current goals, unless those events hold some significance for chronically active goals (e.g., a person's name in the Mack and Rock studies). Even more interesting is the failure of what was previously believed to be a perceptual universal—the ability of unique objects to “pop-out” of a visual display (cf. Treisman, 1988). Pop-out effects have been assumed to be automatic because pop-out is insensitive to the number of distracter items (e.g., a red circle is noticed among a group of green circles independent of the number of green circles). The Mack and Rock studies show items only pop-out if they are relevant to current processing goals. People are often blind to that which is irrelevant for current processing goals. It is this perceptual irrelevance that often leads to failures in perception, as is the case when a motorist fails to see a pedestrian, bicyclist, or an animal prior to a traffic accident.

Change Blindness. Change blindness is the inability of a person to notice a change in a scene if the change occurs while there is a visual disruption (e.g., camera pan, eye blink, saccadic eye movement) (Simons & Levin, 1997). In one of the more compelling examples of change blindness, people are approached by a confederate and asked for directions (Simons & Levin, 1998). During the conversation, two confederates carry a door between the respondent and the original confederate is replaced by a different person (i.e., one of the people behind the door switches places with the confederate). Subsequently, only 47% of the respondents notice the confederate has changed. In a second experiment, Simons and Levin find that only 35% of the respondents notice their conversation partner has changed if the confederates are from a different social group than the respondent. Other demonstrations involve trying to detect changes in a scene that changes slowly over a 20 to 30 second period. People show a remarkable inability to notice changes including adding or deleting a building from a street scene, adding or deleting a road from a corn field, or changing the color of one of four people's shirts (Simons, Franconeri, & Reimer, 2000).

Change blindness is often attributed to a person's inability to notice important details about the initial actor or scene (Simons, Reimer, & Franconeri, 2000). What is missing from this explanation is why some people perceive detail and others do not. It may be the case that the detail of perception is sensitive to the goals accompanying the perceptual experience. For example, when a person is stopped and asked for directions, the enquirer is often perceived at a general level (e.g., a white, male, college-aged stranger). This classification might rely on additional details (e.g., age, hair length, type of clothing), although these details need not be perceived directly (i.e., a classification of a college student relies on a perception of t-shirt, though not a specific type of t-shirt). As long as these features remain consistent for a level of classification (i.e., ethnicity, gender do not change), people will not notice a change in the conversation partner. In contrast, if an enquirer is an attractive person of the opposite sex, the perception may be more detailed owing to goals associated with social interaction, and changes in the conversation partner may be more easily noticed. In other words, if the change in the person or scene does not violate the feature codes and concepts used to generate the perception, a reality determined by the person's processing goals, the change will not be noticed.

The literature on inattention blindness and change blindness implicitly assumes that a person must be consciously aware of an event if it is going to have an influence on their behavior. Recall that Marcel referred to this as the fallacy of the identity assumption (i.e., cognition and conscious experience are not one in the same). It may be more reasonable to assume that perception is a subconscious act which may, or may not, lead to a conscious experience. Thus, the demonstrations of perceptual blindness could be interpreted as evidence that many types of subconscious concepts are being generated (e.g., “gorilla concept”), but that concepts irrelevant to the task are not used to guide behavior or conscious experience. When subsequent questions are asked about these

“ignored” concepts, they are not fluent and the person does not experience a feeling of memory (Whittlesea & Leboe, 2000). Admittedly, this is evidence of a null effect of perception on conscious experience. Yet, the evidence is interesting because most people claim they would be aware of the changes in their environment (cf. Levin, Momen, Drivdahl, & Simons, 2000) and, in fact, might have been if they had different processing goals. In fact, it is a person’s failure to understand that processing goals influence perception that results in a person’s disbelief that they could be susceptible to change blindness.

Consumer Applications. Demonstrations of perceptual blindness could be viewed as cute, anomalies in human perception. Yet, these same perceptual principles are prevalent in consumer behavior. For example, consider the finding that people are quite sensitive to price changes (Greenleaf 1995; Kalyanaram & Winer, 1995), yet cannot report the price of an item immediately after viewing it (Dickson & Sawyer, 1990). One explanation for these findings is that the goal of the price checking task is a comparison of the list price relative to a memory-based or context-based price standard. Hence, the perception of the price is more likely to consist of a perception of *higher than*, *lower than*, or *the same as* the list price. Also, consider the finding that increasing the size of an ad is effective in yellow page advertising (the claim is a standard part of the yellow page sales force support materials), but is fairly ineffective in feature advertising (Pieters, Wedel, & Zhang, 2005). In yellow page advertising, the reader’s goals are consistent with the perception of all of the ads on a page, hence a larger ad draws initial attention and the ad is perceived. In feature advertising, the perceptual goals of most readers are inconsistent with the content of an ad. An ad will not be perceived even if it does receive a limited amount of attention owing to its size. Hence, the impact of ad size and other attention drawing factors is dependent on the goals of the viewer.

Nonconsciously Mediated Behavior

Volitional Behavior. There is considerable evidence that postural adjustment, proprioception (i.e., knowledge of body’s location in space), athletic movements, etc., can occur without the participation of conscious experience. These events are often regarded as over learned behaviors that have become automatic. Rarer are demonstrations that people can engage in volitional behavior without the participation of any conscious experience. Yet, these demonstrations do exist. For example, the Titchener illusion occurs when people perceive a constant-sized disk to be larger when surrounded by small disks as compared to large disks. Despite the perceptual illusion associated with the two presentation formats, grip size is constant when people attempt to grasp the disk (Aglioti, DeSouza, & Goodale, 1995; cf. Glover, 2002). Similarly, if a to-be-touched object is moved while the eyes are in saccade, the hand is redirected to complete the touch, even though the person is not consciously aware of the new location (i.e., does not know the object has moved) (Bridgman, Lewis, Heit, & Nagle, 1979). The implication is that conscious experience is not being used to actively guide motor behavior. Instead, motor control systems are responding to nonconscious perceptions concerning the object.

What is interesting about the demonstrations involving the Titchener illusion and in-saccade object perception is that the concept that guides behavior has the potential to compete with the concept that supports the conscious experience, yet it does not. This lack of interference between the two concepts may be a consequence of the two concepts supporting different goals. The perception associated with the motor act supports the goal of picking up the disk. The perception associated with conscious experience supports the goal of communicating with others. To the extent that all people experience illusions in a similar manner, it is reasonable that the conscious experience

associated with the task should be illusory. In other words, people see and accept the illusion because they expect others will have the same experience.

Mimicry. Chartrand and Bargh (1999) show that people mirror the behaviors of others. For example, Chartrand and Bargh have a confederate engage in face rubbing or foot shaking and show that interaction partners are prone to mimic these behaviors. Chartrand and Bargh argue that there is a perception-behavior link in that the perception of a behavior also primes the motor representation of that behavior. As a consequence, the behavior becomes more likely to be initiated at some time in the near future. Chartrand and Bargh later show that these mimicking behaviors lead to greater liking of the mimicker by the mimickee and propose that mimicry acts like a social glue that promotes communication. What is critical across all of their studies is that participants have no conscious intent to mimic.

Mimicry has also been observed in infants. Children as young as 6-weeks-old can mimic the tongue protrusions, mouth openings, and head movements of their caregivers (Meltzoff & Moore, 1989, 1994; cf. Anisfeld, 1996). Interestingly, infants only mimic behaviors that already exist in their behavioral repertoire. It has been claimed that this mimicry occurs because of mirror neurons, neurons that are common to the perception and execution of a behavior.⁸ Mirror neurons have been shown to be involved in the mimicking behavior of macaque monkeys (Rizzolatti & Arbib, 1998) and infants (Buccion, Binkofski, & Riggio, 2004). Mirror neurons have also been shown to allow for the coordinated representation of perceived movement, executed movement, and sounds accompanying the movement (Kohler et al., 2002), the implication being that the cognitive system can execute acts in response to a verbal cue without the participation of conscious experience.

It is important to recognize that mimicry is selective. For example, participants in the Chartrand and Bargh (1999) studies do not mimic the positioning of a confederate's feet or hands. It is also unlikely that the participants would mimic the confederate's direction of gaze, posture in the chair, or method of pointing, unless these acts were communicatively relevant. In fact, the majority of the confederate's behaviors are not even perceived because they are irrelevant to the goals of the conversation. In other words, the participant's interaction with the confederate provides an opportunity to isolate a large number of concepts, of which only a small number will be selected by the participant. Selected concepts do become more likely to guide future behavior, although the reasons for this mimicry are debatable (cf. Dijksterhuis, Smith, van Baaren, & Wigboldus, 2005; Janiszewski & van Osselaer, 2005).

Subliminally Primed Perception. One of the more robust findings in perception is the influence of expectations on perception (Stroop, 1935). For example, people that have been primed to perceive letters (numbers) will name an ambiguous stimulus (e.g., B) as a letter (number) (Bruner & Minturn, 1955). The implication being that recent perceptions can influence current perceptions. This principle is often apparent in demonstrations of subliminal priming. For example, Bargh and Pietromonaco (1982) found that people subliminally primed with hostile words judge an ambiguously described person to be more hostile than people subliminally primed with neutral words. Subliminal priming can also influence perceptions of seemingly unrelated events. For example, Bargh, Chen, and Burroughs (1996) use a computer to subliminally present a picture of a either a young African American or young Caucasian face prior to each of 130 trials in a boring classification task. On the 130th trial, the program fails and the experimenter informs the participant that the task will have to be repeated. Participants exposed to the African American prime react with greater hostility to the computer failure. These findings, and others (cf. Dagenbach, Carr, & Wilhelmsen, 1989; Draine & Greenwald, 1998), have been interpreted as evidence that subliminal stimuli can prime memory and bias subsequent judgments.

Recent research on subliminal priming suggests the process of subliminal priming is much more complex than previously believed. It may be the case that subliminal primes encourage the creation of nonconscious perceptions and these perceptions then bias subsequent perceptions. To appreciate this distinction, consider the recent findings of Abrams and Greenwald (2000). Abrams and Greenwald had participants classify 12 unambiguously pleasant (e.g., virtue, cheer, angel, warm) and 12 unambiguously unpleasant words (e.g., bile, smut, fraud, death) as “positive” or “negative” using a speeded classification task. After 192 practice classification trials, participants engage in 288 priming trials in which a one of the 24 parent words subliminally precedes one of the other parent words. Finally, participants engage in 288 hybrid priming trials in which a hybrid of the pleasant (e.g., virtue + cheer = *vireer*) or unpleasant (e.g., bile + smut = *biut*) words subliminally precedes one of the 24 target words. As expected, Abrams and Greenwald find that participants make classification errors when a subliminal prime and a target word are inconsistent in valence. More interestingly, participants continue to make these classification errors when the primes are hybrids (e.g., *biut* prime encourages the classification of a pleasant word as negative). A subsequent study shows that people are sensitive to the original valence of the words from which the hybrid was constructed, not the meaning of the hybrid. For example, if *smut* and *bile* are combined to create *smile*, the prime behaves as a negative, not as a positive, prime. A final study shows that primes only exert an influence if they are classified in the initial practice trials.

Abrams and Greenwald (2000) provide a number of findings consistent with the claim of goal-directed perception. First, processing goals (e.g., classify a word as positive or negative) can encourage a person to generate a perception (e.g., a valenced classification) that is independent of the default perception (e.g., semantic meaning associated with the more common use of the stimulus) as determined by the likelihood principle. Second, people can learn to use parts of words to make valenced classifications, much in the same way they use parts of words to make inferences about the identity and/or meaning of the word (e.g., Kouider & Dupoux, 2004). Since perception is the induction of meaning from a neural activation pattern, parts of the pattern have the potential to generate the same meaning as the entire pattern, assuming the parts are unique. Third, people are most sensitive to their most recent perceptual act. In Abrams and Greenwald (2000), people practice classifying the parent words as positive or negative on eight occasions prior to the whole-word and hybrid priming trials. Thus, the subconscious perception of the prime is likely to be its classification, not its semantic meaning. Fourth, the valenced subconscious perceptions can only bias judgments for which these perceptions have relevance. When people have not been trained to classify the valenced word in the training trials, the nonconscious perception is likely to be semantic. The semantic perception has little influence on the subsequent perception that supports the valence classification of the target word, so it exerts no influence.

There are other curious findings in the semantic priming literature that are consistent with the goal-directed perception perspective. First, subliminal priming effects are sometimes limited to situations where the participant is aware that there are subliminal primes. For example, Kouider and Dupoux (2004) observe a Stroop priming effect only when respondents are aware that there is a subliminal priming procedure. Thus, it may be that subliminal perceptions do not exert an influence on judgments and behavior unless the goals of the processing task dictate their usage. Second, subliminal priming effects are sometimes limited to situations where the prime is consistent with the motivations of the individual. For example, Strahan, Spencer, and Zanna (2002) show that thirst related subliminal primes enhance the consumption of beverages for people that are thirsty, but not for people that are not thirsty. Again, it appears as if the prime must be consistent with the goal if it is going to influence a behavior (i.e., more consumption) or experience (i.e., experiencing the beverage as thirst quenching).

Implicit Learning. There is a fair amount of evidence that people can execute behaviors without an accompanying verbal commentary. Automatically learned responses comprise a large portion of these behaviors (cf. Bargh & Chartrand, 1999; Shiffrin & Schneider, 1977). There are also automatic responses that are either learned incidentally (i.e., without the conscious awareness of the rule) or learned better incidentally. For example, people can learn to predict more preferable outcomes without knowing the reason for their prediction. Bechara et al. (1997) had people pick monetary outcomes from four decks of cards, with decks A and B providing high variance outcomes that had a negative mean value and decks C and D providing low variance outcomes that have a positive mean value. People learned to favor the C and D decks, but were not aware of their preference. People were also unaware that they had heightened skin conductance responses to decks A and B (i.e., a somatic marker), a nonconscious signal to avoid these decks (but see Tomb et al., 2002). People can also learn procedural knowledge and artificial grammars without being aware of the rules governing these patterns (e.g., Lewicki, Hill, & Bizot, 1988; Reber, 1967, 1989; cf. Gomez & Schvaneveldt, 1994). In fact, instructions to actively use conscious processes to learn procedural knowledge and artificial grammars reduces the effectiveness of learning (Reber, 1976).

Consumer Applications. The key insight from these findings is not that consciousness plays a limited role in directing behavior, but that currently active goals combine with the activation initiated by the environment to direct behavior. For example, consider the large number of demonstrations of framing effects (Kahneman & Tversky, 1979; Levin, Schneider, & Gaeth, 1998). Framing effects are interesting because they seem to violate the assumption that there should be a context-free representation of information. Yet, it is odd that researchers would expect a context-free representation. Contextual effects on perception form the foundation of many theories of cognitive and social judgment (e.g., range theory, adaptation level theory, assimilation-contrast theory). In fact, Kahneman (2002) argues that framing effects are robust because they are perceptual. People generate a perception that is consistent with a frame, and fail to generate an alternative perception, because perception is sensitive to the information in the environment.

Consciously Mediated Behavior

The Illusion of Conscious Will. Daniel Wegner (2002) argues that many behaviors feel like they are determined by conscious will, but are not. People have the illusion of the conscious control over behavior because they make causal inferences by attending to the contingency between the act of doing and the conscious experience of doing. What people fail to realize is that there are situations in which they behave, but have no conscious experience of doing (e.g., automatic behaviors) and there are situations in which they have a conscious experience of doing, but are not actually in control of their behavior. People tend to ignore these later classes of behavior, thus perceive there to be a perfect correlation between the conscious experience of doing and the act of doing. In fact, this correlation is spurious. The real causal agents responsible for the conscious experience of doing and the act of doing are nonconscious perceptions.

Evidence that people mistakenly believe they are in control of their behavior is sparse because it is uncommon to look for such evidence. Still, there is some support for the hypothesis. For example, Brasil-Neto et al. (1992) asked respondents to move their left or right forefinger when they heard a click. During this task, magnets were turned on and off over motor areas on the left/right side of the brain. Although the magnets determined which finger was moved in response to the click, subjects claimed to voluntarily select the finger to be moved. Wegner observes that people make similar mistakes about systems outside of their body. Many people believe they can influence

a random system (i.e., exhibit skill in a game of chance), a stable system (i.e., will a car to start), or an independent event (i.e., influence the outcome of a sporting contest).

Conscious Thought and Behavior. People often try to introspect in order to understand the reasons for their behavior. In many cases, introspection provides no insight into the reasons for behavior, except to the extent that the prior culturally-based explanations of behavior help a person to generate potential causes (Nisbett & Wilson, 1977; Wilson, 2002). To support this claim, consider the infant that attempts to “explain” its discomfort owing to a warm room, teething, or a diaper rash. If the child cannot yet perceive these causes as distinct perceptual events, they cannot be perceived as causes of the discomfort. As the child matures, it is taught reasons for its behavior, some accurate and some not (Nisbett & Wilson, 1977). Nonetheless, the causes and responses to the environment exist long before the child can understand their relationship. This failure to understand cause-behavior relationships persists into adulthood, where people make a variety of misattributions about the causes of their behavior (Ross & Nisbett, 1991).

Wilson and colleagues (cf. Wilson 2002; Wilson & Dunn 2004) have argued that the failure of introspection is apparent in people’s inability to state the reasons for their behavior. In fact, stating reasons for behavior often alters behavior. For example, analyzing reasons for behavior lowers the correlation between a person’s feelings and actual behavior (Wilson & Dunn, 1986), predicted and actual behavior (Wilson & LaFleur, 1995), and satisfaction with his/her choices (Wilson et al., 1993). Thus, it may be the case that conscious experience can be used to activate goals that guide decisions about behavior, but these rule-based behaviors may not be equivalent to the behavior that would have been initiated by the more basic associative system that guides most behaviors.

The work of Wilson and colleagues suggests that conscious thoughts can create a bias. In some ways, this is the equivalent of stating that a secondary task interferes with primary task completion, an obvious point. Yet, what is interesting about Wilson’s evidence is the derogating conscious experiences were related to the task being performed. There is similar evidence that conscious monitoring can inhibit athletic performance (Hefferline, Keenan, & Halford, 1959), reduce the fluency of spoken language (Woods, Miltenberger, & Flach, 1996), and impair the performance of any over-learned behavior (Baumeister, 1984). It may be that conscious experience primes other feature codes and concepts that somehow get incorporated into the behavioral responses that might have naturally occurred. These additional feature codes and concepts make performance different and in many cases worse. In this type of system, consciousness has no special status in directing behavior, except that it can make certain feature codes and concepts more available and increase the likelihood that they are used in perception.

Motor Responses and Behavior. Two of the assumptions of the goal-directed model of perception are that the perceptual system uses stimulation from all sensory systems to generate perceptions and that observation of one’s personal behavior creates neural activation (i.e., feature codes and concepts) for subsequent perceptions. Both of these assumptions are apparent in the influence of motor acts on judgment. For example, Strack, Martin, and Stepper (1988) have respondents hold a pen between their teeth (simulating smiling) or between their lips (inhibiting smiling) while judging the humor of cartoons. Smiling respondents judge the cartoons to be funnier. Similarly, Zajonc, Murphy, and Inglehart (1989) find that reading a script containing many words with the vowel “e” (facilitating smiling) led to a more enjoyable experience than reading a script containing many words with the vowel “ü” (inhibiting smiling). Smiling, or not, has also been shown to influence judgments of perceived guilt (Bodenhausen, Kramer, & Süsser, 1994) and an ambiguous social situation (Martin, Harlow, & Strack, 1992). In each of these cases, the act of smiling or not generates stimulation that is incorporated into subsequent perceptions.

There are numerous other demonstrations of the influence of motor movements on subsequent behavior that suggest interesting interactions among “cognitive systems.” For example, in the realm of memory, moving one’s head vertically (i.e., nodding yes) while viewing positive and negative words enhances memory for the positive words, whereas moving one’s head horizontally (i.e., nodding no) enhances memory for the negative words (Förster & Strack, 1996). In the realm of reflexive eye blinks, eye blinks are slower when a startle response is to a positive picture than a negative picture (Lang, Bradley, & Cuthbert, 1990). In the realm of experiences, frowning the brow induces feelings of mental effort (Strepper & Strack, 1993) and receiving positive feedback while sitting upright, as opposed to slumped, increases feelings of pride (Strepper & Strack, 1993). All of these demonstrations suggest the execution of a motor behavior provides neural activation that is used to generate perceptions that support future behavior and experience.

Impulsive Behavior. Research on impulsive behavior suggests there are two classes of behavior: impulsive behaviors that are gratifying, easily executed, and detrimental to our long term well-being (overeating, overspending, excessive drinking) and countervailing control behaviors that are difficult to monitor and execute (e.g., responsible eating, spending, and drinking). Impulsive behaviors are often claimed to “result from the encounter between a motivation and some activating stimulus” and to “occur without intention or plan” (Baumeister, 2002, p. 670). Impulsive behaviors are automatically initiated by a variety of stimulus cues, some that are novel, and control behaviors can only override the impulsive behaviors provided there are enough resources available to execute the control (Baumeister et al., 1998).

The goal-directed perspective on perception can be used to explain two events that are inconsistent with this currently popular explanation of impulsive behavior. First, available stimuli do not always result in impulsive behavior, even in the absence of conscious control. People do not overindulge every time they are in the presence of stimuli that have been inviting in the past, yet do occasionally overindulge in the presence of a novel stimulus. This apparently inconsistent behavior may be attributed to the fact that perception relies on currently active goals. For example, consider an overeater in the context of a party. If the overeater is actively involved in a conversation, goals associated with the conversation may preclude the person from perceiving the inviting food on an adjacent buffet. The conversation goals are more accessible relative to the oral gratification goals, thus perception is driven by these conversation goals. Yet, if the conversation wanes, the oral gratification goals may become more accessible, owing to feature codes associated with the food prime, and the food on the buffet becomes more likely to be perceived and eaten. Alternatively, in the absence of any motivating goal (i.e., boredom), people perceive the most practiced meanings in their environment owing to the likelihood principle. Perception of the food can activate the oral gratification goal and promote eating.

Second, Baumeister also claims that conscious control can limit indulgence. For example, suppose that a person perceives food in the environment and becomes more likely to indulge owing to active oral gratification goals. Also assume that the perception of food activates the language concept of “don’t eat,” a conscious description associated with prior instances of overindulgence. If the language concept is tied to self-presentation and health goals, then thoughts of not eating can prime goals that make other, nonindulgent behaviors more valued. For example, a person with active oral gratification and health goals may choose a healthier snack from the buffet.

Consumer Applications. The literature on consciously mediated behavior suggests that people have a difficult time explaining why they behave the way they do and that attempts at explanation and/or monitoring can alter behavior. If this is so, there should be a premium placed on investigations that focus on behavior, as opposed to the measurement of constructs that are hypothesized to

influence behavior (unless the verbal behavior is meaningful in its own right). Second, there should be a premium on investigations that show mediation by experimentally manipulating a process, as opposed to measuring the process. Third, it may be interesting to consider the potential research agenda that might follow from the conclusions that conscious thought does not cause behavior, except through its ability to prime subsequent subconscious perceptions. This viewpoint implies that thought is an experience similar to an emotional experience. Value can be conceptualized as the premiums people place on different types of thought experiences. Marketers are successful because they can link their products, or the consumption of their products, to valuable thought experiences. The recent movement toward visual, image-based advertising, and away from benefit advertisement (cf. McQuarrie & Mick, 2003) is consistent with this perspective. McQuarrie and Mick (2003) suggest that advertising uses imagery to teach consumers about product meaning and the appropriate conscious experiences that should accompany consumption.

Similarly, consider the interest in hot cognition and its influence on thought (Dai & Sternberg, 2004; Mayer, Salovey, & Caruso, 2004), product appraisal (Yeung & Wyer, 2004), and decision making (Allen, 2002). Researchers who work in these paradigms have a difficult time quantifying causal agents because people cannot always communicate about hot perceptions. Yet, these perceptions certainly do influence behavior. In these situations, language, and in all likelihood conscious experience, may not be diagnostic of the nonconscious perceptions that are guiding behavior. The difficulty people have when trying to articulate the meaning of emotional decisions or possessions is apparent in their protocols about these events (e.g., Allen 2002; Price, Arnold, & Curasi, 2000).

CONCLUDING THOUGHTS

The objective of this chapter has been to encourage consumer researchers to embrace the variance of perceptual experience as a potential source of insight into consumer behavior, as opposed to unwanted error. Although the higher order processes that manipulate “perceptual outputs” are interesting and worthy of the extensive study they have received, the factors that lead to the selection of a single perception, or a collection of related perceptions, are also worthy of study. I anticipate that there are a number of areas that could benefit from incorporating the perspective of perceptual variance. I discuss two mainstream areas in an effort to illustrate how the ideas discussed in this chapter might be implemented.

Brand Relationships

Fourier (1998) discusses the importance of the relationships consumers develop with brands. Fournier’s work is some of the most highly cited over the past 5 years, yet it has not yet been embraced by many mainstream information processing researchers. Perhaps this is because these researchers do not have relationships with brands, using the more formal definition of an interpersonal relationship (i.e., reciprocity). Yet, in some way, this misses the key conceptual insight of Fournier’s contribution. An interpersonal relationship is defined by a series of interactions, all of them unique. A brand or product relationship can also be defined by a series of consumption experiences, all of them unique. These consumption experiences with a brand or product can vary, even though the product is standardized owing to mass production. The consumption experiences are supported by subconscious feature codes and concepts. It is the variety and use of these concepts that creates the relationship.

The second conceptual insight afforded by Fournier’s analysis is that it is the perceptual variance at the conscious level, not the perceptual invariance at the subconscious level, that defines the

consumer's relationship with the brand. A relationship is not simply summation of satisfactory and dissatisfactory experiences. It is the rich collection of varied conscious experiences (supported by subconscious concepts). In the absence of a conceptualization of perceptual variance, Fournier develops summary terms for the collection of conception experiences. The next major advance in the brand (product) relationship literature will come when marketers learn how to manage these consumption experiences. The key will not be "having a conversation with the consumer," as some have suggested. Instead, it will be learning how to encourage the consumer to have the experiences that make the product an integral part of their lives. Such an understanding will allow marketers to encourage consumers to be loyal to a product (e.g., Coke), a product category (e.g., seafood), an activity (e.g., mountain biking), or a belief (e.g., conservatism). Although these ideas are certainly a part of our history of research in consumer behavior (e.g., Holt, 2002; Levy, 1981), they have largely been ignored by researchers with a more cognitive, positivist orientation to their research program.

Customer-Based Brand Equity

Customer-based brand equity may be another area of inquiry that could benefit from the concept of perceptual variance. Consider the conventional wisdom about the source of customer-based brand equity. More positive experiences lead to more brand equity (Janiszewski & van Osselaer, 2000; Keller, 1993). Yet, the number of positive experiences may not be the sole source of brand equity. The variability in positive experiences may also contribute to brand equity. Although Keller (1993) refers to this variability of experience, he uses the variability of experience to support enhanced recall of the brand name, an increased likelihood of judging the brand appropriate for different consumption situations, and an increased differentiation of the brand. Yet, there are more consequences of variability than memory, contextual appropriateness, and differentiation effects. For example, soft drinks and deodorants both offer variability in experience, but successful soft drink brands have more equity on a per customer basis than successful deodorant brands. The difference between the variability of the experiences among these two brands is that the soft drink experiences are more varied over time (i.e., more complex). In a Gibsonian sense, the perception must be culled from an internal and external environment that is more information rich. This may be why ritual consumption often involves products that provide an opportunity for many motor acts during preparation and consumption. This complex consumption process allows for a highly nuanced experience. It is this interplay between motor behavior and conscious experience that give the experiences, and by extension the product, a richer meaning.⁹ This richer meaning is the source of equity. More importantly, it is likely that certain mixtures of positive experiences (e.g., thoughtful, extended, affectively mixed, etc.) may lead to more equity than a simple stream of consistently uniform positive experiences.

Summary

The discussion of the potential opportunities to explore the consequences of perceptual variance might be interpreted as a call for more research in the domains traditionally associated with consumer culture theory (Arnold & Thompson, 2005). To some extent it is, but with three caveats. First, there is no reason that the study meaning should be relegated to the methodological techniques commonly used to investigate consumer culture theory. Experimental techniques can be effective at providing insight into meaning creation, as has been illustrated in the priming literature. Second, to some extent, much of consumer culture theory has focused on common meanings that

are shared among individuals, not on the diversity of meanings experienced by a single individual or group of individuals. Although looking for commonalities in the diversity of experiences among people may seem like a monumental task, there are certainly exemplars of these types of investigations in consumer research (e.g., Muniz & O'Guinn, 2001; Sirsi, Ward, & Reingen, 1996). Third, since perception and behavior may be inherently linked, there is an opportunity to assess how meaning evolves with consumption and brand communication. Consumption and communication experiences contribute to the meaning of the brand. Hence, research that investigates the influence of consumption (and communication) context, ritual, variability, and experience on meaning is needed. Given the inherent difficulty of self-reports, my hope is that this research will involve the manipulation of consumption and communication episodes in an effort to understand how these factors influence meaning.

NOTES

1. Empirism refers to the doctrine that abilities are learned through experience. Empiricism refers to the claim that knowledge should be generated from observation (data) as opposed to through reason.
2. Pomerantz and Kubovy (1986) offer an excellent review of the Gestalt approach to perception. The Gestalt view assumes perceptual organization relies on the innate structure of the brain and that the goal of perceptual research is to document perceptual laws. The gestalt approach to perception is not included in this review.
3. William James is the notable exception to this generalization. James felt some perceptual experiences were hard-wired (e.g., emotions) and other perceptual experiences were mental events that aided the survival of the species.
4. Wilson (2002) observes that the visual system sends 10 million pieces of information to our brain per second, but that our brain can only perform 40 active operations per second. If the perceptual system is integrating elements, it would take 70 hours to generate a perception. Although automaticity could be used to solve this integration problem, automaticity cannot account for perception among infants or perception in novel environments.
5. Connectionist models use weights to define the relationship between the receptors that are activated owing to stimulation of the senses and the binary units that represent a concept. The connection weights, not the physical pattern of the distribution, are the concepts. This additional complexity is not pertinent to the arguments made in this chapter.
6. For prior demonstrations of perceptual blindness, see Becklen and Cervone (1983) and Neisser and Becklen (1975).
7. Videotapes of stimuli used to study inattention blindness and change blindness can be found at http://viscog.beckman.uiuc.edu/djs_lab/demos.html.
8. See <http://www.pbs.org/wgbh/nova/sciencenow/3204/01.html> for a 14-minute discussion of mirror neurons.
9. Again, it is the feature codes and concept that support conscious experience, not the experience itself, that are the causal agents.

PERSUASION, ATTITUDES, AND SOCIAL INFLUENCE

15

Attitude Change and Persuasion

CURTIS P. HAUGTVEDT

JEFF A. KASMER

Kasmer Associates

Allport (1935, p. 798) characterized attitude as “...probably the most distinctive and indispensable concept in ... social psychology.” Allport and other theorists viewed attitudes as a fundamental contributor to how persons deal with the world around them. Thomas and Znaniecki (1918) describe social psychology as the scientific study of attitudes. Contemporary researchers and theorists share the view that attitudes have very important influences on perceptions, thoughts, and behavior at individual, social, and cultural levels (e.g., Eagly & Chaiken, 1993; Greenwald, 1968, 1989). The ways in which attitudes are formed, changed, stored, activated, and used has been the focus of a tremendous amount of research activity in the past 90 years. Our goal in this chapter is to briefly outline the history of research and thinking with regard to attitudes, attitude change, and persuasion. We then discuss selected studies that have advanced and/or challenged theoretical perspectives. We end our chapter with a brief summary of some exciting new developments in the study of attitudes, attitude change, and persuasion in social and consumer psychology.

ATTITUDE AND ATTITUDE MEASUREMENT

A commonly used definition is that attitudes are general evaluations of objects, issues, or people (Petty & Cacioppo, 1981); Fazio views attitudes as object-evaluation associations (chapter 16, this volume). Attitudes are contrasted with other constructs such as “affect” (see chapters 10, 11, and 43, this volume; Petty, Cacioppo, & Kasmer, 1988). Fleming (1967) provides an historical view of the term “attitude.” Attitude formation and attitude change (e.g., Palmerino, Langer, & McGillis, 1984; Petty & Cacioppo, 1986a) can be thought of as points along a continuum. Consistent with other writing, for our purposes, the terms will be used interchangeably (cf., Crano & Prislin, 2006; Petty, Schumann, Richman, & Strathman 1993; Petty & Wegener, 1999).

Prompted by issues raised by psychologist Floyd Allport, L. L. Thurstone boldly titled his (1928) paper: “Attitudes can be measured.” In the paper and other work, he described the extensive psychometric methods that could be used to measure the construct of attitude. In part, because of the time and effort needed to construct a Thurstone scale, it is rarely used. Over the years, researchers have employed many techniques to assess attitudes (see Petty & Cacioppo, 1981; Krosnick, Judd, & Wittenbrink, 2005, for descriptions).

In contemporary research, popular methods to assess attitudes in experimental studies are the Likert scale and the semantic differential. Thus, for example, Petty, Cacioppo, and Goldman (1981, p. 850) assessed attitudes toward comprehensive exams with “four 9-point semantic differential scales (good/bad, beneficial/harmful, foolish/wise, and favorable/unfavorable). Next, on an 11-point scale anchored by 1-“do not agree at all,” and 11-“agree completely,” subjects rated the extent to which they agreed with the proposal requiring seniors to take a comprehensive exam before graduating.” The scores were then standardized and averaged to form a single measure for attitude toward senior comprehensive examinations. Similarly, Petty, Cacioppo, and Schumann (1983, p. 140) assessed attitudes toward a product with “three nine point semantic differential scales anchored at -4 and +4 (bad-good, unsatisfactory-satisfactory, and unfavorable-favorable).” Petty et al. (1983) combined the attitude data across the three scales to assess the attitudes toward the product. Reviewing details of the advantages and disadvantages of various measurement techniques are beyond the scope of this chapter; readers interested in learning more about the topic are referred to Krosnick, Judd, and Wittenbrink (2005) for a review of the importance of attitude measurement issues in contemporary research.

Although many dimensions of attitudes were mentioned in early theorizing and research, changes in technology and measurement methods have ignited interesting discussions regarding the difference between indirect (implicit) and direct (explicit) measures of attitudes. These methods are detailed in chapters by Jones and Fazio (chapter 11, this volume), Vargas (chapter 18, this volume) and Perkins, Forehand, Greenwald, and Maison (chapter 17, this volume). Continued research on classic issues and the development of new perspectives that build on and challenge existing empirical research and theoretical frameworks keep the topic of attitude change and persuasion on the center stage of social and consumer psychology research.

ATTITUDE CHANGE AND PERSUASION

Carl Hovland and his colleagues at Yale were instrumental in developing the first set of systematic studies on variables relevant to attitude change (e.g., Hovland, Janis, & Kelley, 1953; Hovland & Weiss, 1951). One of the milestones in the attitude change and persuasion literature was the evolution of the Yale message learning approach to the cognitive response approach developed and advocated by Timothy Brock (a student of Carl Hovland) and his colleagues at Ohio State University (e.g., Greenwald, 1968; Petty, Ostrom, & Brock, 1981). Richard Petty (1977; Petty & Cacioppo, 1981) extended and qualified the cognitive response approach with the Elaboration Likelihood Model. While the cognitive response approach viewed all attitude changes as requiring a relatively high degree of elaboration, Petty and Cacioppo postulated that attitude change could also take place with relatively little elaboration of message content. Their 1981 book focused on describing where various theoretical perspectives and interpretations of empirical studies might fall on an elaboration continuum. The final chapter of their book contains a description of their model. Petty’s 1977 dissertation contains a schematic and description of the model. A book by Petty and Cacioppo (1986a) and a chapter (“Advances in Experimental Social Psychology,” Petty and Cacioppo, 1986b) provide detailed postulates of the Elaboration Likelihood Model (ELM). See also Petty, Priester, and Wegener (1994) for a more recent summary of research on cognitive processes in the ELM.

Contemporary research on attitude change and persuasion has been dominated by dual route perspectives (e.g., Petty & Cacioppo, 1981, 1986a; Chaiken, 1987). Dual route models and their implications will be discussed in more detail later in this chapter.

Research on attitudes and persuasion played a central role for the relatively young field of consumer psychology (see chapter 1, this volume). Reviews of much of this work can be found in consumer psychology chapters appearing in the *Annual Review of Psychology* approximately every 3

to 4 years (e.g., Kassarjian, 1982; Bettman, 1986; Loken, 2006). Reviews of social influence (Cialdini & Goldstein, 2004) and attitude change (Crano & Prislin, 2006) will also be of interest to consumer psychologists.

Contemporary research and theorizing still draws heavily on the fundamental measurement and methodological issues addressed in pioneering work in attitude change and persuasion. Petty (1997) provides a review on how research on attitude change and persuasion evolved from single-effect and single-process assumptions to contemporary views of multiple effect and multiple process models. Models such as the Elaboration Likelihood Model (ELM) and Heuristic Systematic Model (HSM) have generated a great deal of research in the past 30 years. In the following sections, we highlight just a few of the areas of research. In addition, we review some of the debates that have emerged in the literature that have been stimulated by the development of models like the ELM. Readers unfamiliar with the attitude change and persuasion literature are encouraged to review Petty and Cacioppo (1981) and Chaiken and Eagly (1993).

CONSEQUENCES OF ATTITUDE CHANGE PROCESSES

Consumer and social psychologists share the goal of developing persuasive campaigns, interventions, and strategies that increase the likelihood of desired outcomes. In most cases, this means a change in behavior. As other chapters in this handbook and other sources describe (e.g., Petty & Krosnick, 1995; Ajzen, chapter 20, this volume), there are many factors to consider with regard to the abilities of attitudes to predict behavior. In this section, we focus on how aspects of the attitude change process are hypothesized to lead to newly formed or changed attitudes relatively more persistent (decay less over time), relatively more resistant (change less in the face of attack) and lead to greater degrees of attitude-behavior consistency.

Petty, Haugtvedt, and Smith (1995) provide a detailed review of an ELM perspective on the consequences of attitude change processes. As they note, the ELM was initially proposed as a means of understanding why in some studies attitude changes could be characterized as relatively strong (e.g., persistent), whereas in other studies the attitude changes could be characterized as weak (not persistent). According to the ELM, persuasion that occurs via the central route to persuasion versus persuasion that occurs via the peripheral route to persuasion can initially lead to equivalently positive or negative (equally extreme) attitudes. Nevertheless, the model specifies that newly formed or changed attitudes as result of central route persuasion should be stronger (e.g., more persistent, resistant, and predictive of behavior; Petty, 1977; Petty & Cacioppo, 1981, 1986a). Central route attitude changes are characterized as resulting in more extensive and integrated structures, whereas peripheral route attitude changes are characterized as resulting in fewer and weaker linkages.

To examine the ELM's attitude elaboration-persistence hypothesis, Haugtvedt and Petty (1992) used the individual difference variable of Need for Cognition (NFC; Cacioppo, Petty, & Morris, 1983) to operationalize motivation to process. While viewing a television program, individuals high and low in Need for Cognition were exposed to a television advertisement for a telephone answering machine in the context of other ads. Importantly, the critical advertisement was pre-tested to contain strong arguments and variables that could serve as positive peripheral cues so that initially comparable attitudes could be developed in both the high and low need for cognition groups. Participants completed product attitude assessments and other questions immediately after viewing the show. Two days later, participants returned to the lab expecting to view and rate another TV show. During this second session, participants completed another attitude assessment and listed their thoughts about the target product. As expected, both high and low need for cognition groups formed equally positive attitudes toward the product in the immediate setting, but the

attitudes of the low need for cognition participants showed significant decay over the 2-day period. That is, consistent with predictions, attitudes of high need for cognition participants were relatively more persistent than those of the low need for cognition participants. In general, high Need for Cognition (HNC) participants should elaborate more on message content when exposed to the initial message, whereas low Need for Cognition (LNC) participants would rely on other factors (such as the number of arguments) to form their attitudes.

In a second study, Haugtvedt and Petty (1992) examined the degree to which newly changed attitudes of high versus low need for cognition participants were able to resist change in the face of a weak attack. Participants were exposed to an initial message about the safety of a well-known food additive. The initial message was pre-tested to contain strong arguments from an expert source. Attitudes were assessed after exposure to the message. Participants were then exposed to an opposing message that contained weaker arguments from a different expert source. Attitudes were again assessed, along with cognitive responses. Because of methodological concerns, cognitive responses were not assessed until after attitude assessment and only after exposure to the second message. Based on pre-testing and prior research, attitudes of HNC participants were expected to be based on elaboration of the initial message content, whereas the attitudes of LNC participants were expected to be based on perceptions on schemata source expertise. Consistent with predictions, although equivalent after the first message, Haugtvedt and Petty (1992) found that attitudes of LNC individuals changed more after exposure to the opposing message than did the attitudes of the HNC participants. Additional analyses provided support for the ELM based process explanation of active resistance by the HNC participants and greater influence of source expertise on attitudes by the LNC participants. A recent study by Wheeler, Petty, and Bizer (2005) suggests that similar processes may be invoked by messages that match self-schema. Because messages that match self-schemata tend to lead to greater elaboration, such attitudes should also exhibit greater resistance to later, opposing messages.

Further support for the elaboration-resistance hypotheses is found in studies by Haugtvedt and Wegener (1994). Using a situational manipulation of the personal relevance of topics in a message order effect paradigm, studies by Haugtvedt and Wegener (1994) showed that participants exposed to an initial message under high relevance were more resistant to an equally strong, opposing, second message.

Studies by Haugtvedt, Schumann, Schneier, and Warren (1994) provided support for the ELM's notion that persistent attitudes can be based on strong cue associations but that such attitudes are likely to change in the face of challenges. Using an advertising repetition paradigm of substantively or cosmetically varied ads developed by Schumann, Petty, and Clemons (1990), Haugtvedt, Schuman, et al. (1994) showed that three exposures to cosmetically varied ads or three exposures to substantively varied ads could lead to equally positive and equally persistent attitudes over a two day period. Nevertheless, when faced with challenges in the delayed setting, attitudes developed from exposure to substantively varied ads were relatively more resistant to change. In sum, equally persistent attitudes can otherwise differ on other important dimensions.

Petty, Haugtvedt, and Smith (1995) note that most studies of attitude-behavior consistency assess the extent to which pre-existing attitudes predict behavior (*cf.*, chapter 20, this volume). Results of such studies can be interpreted as supportive of the ELM's elaboration-consistency hypothesis. Attitudes based on the relatively greater operation of central route to persuasion processes should be based on more elaboration and therefore should be more predictive of behavior than attitudes based on the relative operation of peripheral route to persuasion processes. Petty, Haugtvedt, and Smith (1995) also review studies that focus on how characteristics of persons are associated with greater attitude-behavior consistency (e.g., NFC, self-monitoring etc.).

Importantly, studies can also be interpreted as consistent with the ELM's proposition that newly formed attitudes based on greater elaboration should be more predictive of behavior. For example, data analyses of Petty, Cacioppo, and Schumann (1983) showed that the post advertising exposure attitudes of persons randomly assigned to the high relevance condition were significantly more predictive of purchase intentions than persons randomly assigned to the low relevance condition. Similarly, data from a study on self-relevance and attitude behavior consistency by Leippe and Elkin (1987) showed that the contents of essays written by participants after exposure to a message under high relevance conditions were more consistent with attitudes than persons who had been exposed to the message under conditions of low relevance.

Research on attitude strength consequences such as persistence, resistance, and attitude-behavior consistency have been topics of long-standing interest and research by social psychologists and others (see Petty et al., 1995, for a review). Research guided by the ELM, however, has typically employed manipulations and measures that provide a clearer understanding of the mechanisms underlying the consequences.

Perhaps, in part, because Petty and his colleagues have used extensive literature reviews that include reinterpretations and inferences regarding underlying processes in existing studies, some researchers (and reviewers!) sometimes view the findings of the new studies as "already well-known or well-established." Of course, although inferences about process and reinterpretations of past studies have been used as advocacy for a theory, it remains important for consumer and other researchers to conduct original studies that include measures designed to assess the hypothesized underlying processes. It is also important for consumer psychology researchers to understand the boundary conditions for the various processes and mechanisms (McGuire, 1985). In sum, there are many remaining profitable avenues of inquiry surrounding the important issue of understanding and predicting consequences of attitude change processes. Once established, various research paradigms may be integrated with newer theoretical formulations to better understand the multiple processes by which attitudes may or may not be persistent, resistant, or predictive of behavior (cf., Wegener, Downing, Krosnick, & Petty, 1995; Haugtvedt, Shakarchi, Samuelson, & Liu, 2004).

MULTIPLE ROLES FOR VARIABLES

In the preceding section, we briefly reviewed studies supportive of some of the ELM's postulates related to the consequences of attitude change processes. These consequences are especially important and relevant to consumer researchers and policy makers. Basic descriptions of the ELM can be found in most contemporary consumer behavior textbooks. The Petty, Cacioppo, and Schumann (1983) study is one of the most frequently cited papers from the *Journal of Consumer Research*. Despite the high awareness levels of the basic ELM framework among consumer psychologists, many researchers are often unaware of the more intricate aspects of the model. As an approach to research, the ELM is a good example of a programmatic approach as advocated by William McGuire (McGuire, 1985). As noted earlier, the ELM evolved, in part, out of a critique of the cognitive response tradition of persuasion research. Richard Petty and John Cacioppo, trained as experimental social psychologists, understood the value of standardized research paradigms and a standardized toolbox of messages and measures for initial basic studies. Their initial research challenged existing paradigms and thinking and suggested boundary conditions for prominent theoretical frameworks and established phenomena (e.g., Petty & Cacioppo, 1979) by adding new manipulations and measures. They drew on classic issues in social psychology as a source of materials and utilized newer psychophysiological techniques to assess hypothesized underlying processes (e.g., Cacioppo & Petty, 1983). Building on these ideas, Sanbonmatsu and Kardes (1988) used

a manipulation of physiological arousal to find that a source's celebrity or noncelebrity status was a more important determinant of brand attitudes under high arousal. The postulates of the ELM and the research methods used in ELM studies provide basic and applied researchers with useful guides when developing and assessing persuasion attempts in advertising and other contexts (Haugtvedt & Priester, 1997).

With the general foundation of basic processes and measures established in both the social and consumer psychology research domains, some of the most interesting work using the ELM framework remains to be conducted. Some of this work, in our view, focuses on the issue of multiple roles for variables. In the following pages, we outline some of the initial work that can be seen as supportive of the ELM's multiple roles principles. In addition, we encourage consumer psychologists to consider how the many important variables in the marketplace can and should be examined from a multiple roles perspective. Understanding the roles a variable does or can play has important implications for marketing strategy and advertising decisions (cf., Haugtvedt, Leavitt, & Schneier, 1993; Haugtvedt & Priester, 1997).

Petty, Cacioppo, and Schumann (1983) introduced the ELM to the consumer researchers with an experimental laboratory study that used manipulations of three important components: a manipulation that was designed to influence the motivation of participants (personally relevant vs. less personally relevant), a manipulation of product attribute or argument quality to assess the degree of elaboration (strong vs. weak arguments), and a manipulation of source factors (celebrity vs. noncelebrity sources). Each of these factors was carefully pre-tested before they were combined in the final study. Results of the study showed, consistent with predictions, that the situational manipulation of motivation moderated the extent to which participants elaborated on message content (as assessed by final attitudes) and the extent to which participants relied on celebrity status as a peripheral cue in attitude change. The basic ELM laboratory paradigm illustrated by the Petty et al. (1983) study has been used in numerous attitude change and persuasion studies.

When first exposed to the ELM models and studies, students and researchers sometimes assume that there should be a taxonomy of variables that nicely fit into the various categories of motivation, ability, arguments, and cues. Based on theoretical reasoning, the ELM authors have not endorsed an arbitrary categorization of variables. An important aspect of the ELM is the idea of an elaboration continuum (Petty & Cacioppo, 1986a). The more motivated and able consumers are to assess the central merits of an attitude object, the more likely they are to employ effortful processes and consider all available information. The less motivated and able consumers are to assess central merits of an attitude object, the more they may rely on processes that do not require much effort to arrive at a judgment. Petty and Wegener (1998) describe these processes in detail.

Most relevant for our current discussion is the idea that the ELM does not hold that a given variable will always serve the same role in different persuasion settings. From early descriptions of the ELM, Petty and Cacioppo (1986a) specifically note that any given variable has the potential to influence attitudes by serving as a peripheral cue, an inducement to process, an argument, or a factor that might bias information processing given a specific combination of other factors. Importantly, the role for a specific variable can be specified in advance. In addition, research using the ELM research paradigm can be employed to assess the role that a given variable typically plays for a given group of consumers at a specific time. For example, although some consumer research studies show that brand name can serve as a peripheral cue (see Maheshwaran, Mackie, & Chaiken, 1992), brand name has the potential to be much more than a peripheral cue (Haugtvedt & Rucker, 2002; Haugtvedt & Rucker, 2007). In other circumstances, brand name may induce greater elaboration of message content, or biased elaboration of message content. In other situations, brand name also has the potential to serve as an argument. Importantly, and especially relevant for con-

sumer psychology research, is the likely possibility that the role a brand name plays for a consumer changes over time (based on factors such as greater knowledge, product usage experience, effects of advertising and other marketing communications, discussions with others, integration of affect, etc.). In addition, ELM research paradigms can be used to assess the role that brand name or other marketing factors play in the development or change of consumer attitudes (cf., Haugtvedt, Leavitt, & Warren, 1993; Haugtvedt et al., 1994; Haugtvedt & Priester, 1997). For reviews of and responses to misunderstandings of the ELM's multiple roles postulate and responses to critics of the ELM, readers are referred to Petty, Kasmer, Haugtvedt, and Cacioppo (1987); Petty, Cacioppo, Kasmer, and Haugtvedt (1987); Petty, Wegener, Fabrigar, Priester, and Cacioppo (1993); Petty and Wegener (1999).

In the following pages, we provide a few examples of empirical research that provides support for the ELM's multiple roles perspective. As noted in the previous section, we see many opportunities for consumer psychology researchers to re-examine previous conceptualizations and categorizations of variables when considered in light of the multiple roles perspective.

Petty, Kasmer, Haugtvedt, and Cacioppo (1987) review the results of the Moore, Hausknecht, and Thamodaran's study (1986) and interpret the results as consistent with a multiple roles approach. In their study, Moore et al. (1986) manipulated elaboration likelihood by changing the speed of radio commercials. Results of their study show that the source of the commercial served as a peripheral cue under low elaboration, but as a message argument under high elaboration. Under moderate levels of elaboration likelihood, the source served as a motivator of thinking about the message arguments.

Research has also supported the view that affect can serve in multiple roles (Petty, Cacioppo, & Kasmer, 1988). For example, Petty, Schumann, Richman, and Strathman (1993) measured attitudes toward a pen under conditions of low or high elaboration likelihood. Under conditions of a pleasant TV show context (in contrast to a neutral TV show context), when participants were motivated to think more carefully about the advertisement for the pen because they would have to choose a pen to take home, positive cognitive responses increased as did their positive attitude change toward the pen. On the other hand, when participants were under low elaboration likelihood, they also experienced the positive attitude change, but their positive cognitive responses showed no increase. Relevant to the ELM multiple roles perspective, mood affected attitudes through influencing issue-relevant thoughts under high motivation but had a direct influence on attitudes under low motivation. In a recent publication, Bakamitsos (2006) also provides evidence that affect can serve either as a peripheral cue or as stimulus to thinking.

Comparative advertising formats have also been shown to influence attitude change processes in different ways depending on the nature of participant motivation. In a study designed to examine the influence of comparative versus noncomparative advertising formats, Pechmann and Esteban (1994) were able to create three distinct levels of participant motivation. Using an argument quality manipulation to assess the degree of message content elaboration, Pechmann and Esteban (1994) showed that under low levels of motivation, a direct comparative advertising format served as a peripheral cue; under moderate levels of motivation, a direct comparative format led to greater elaboration of message content; under high motivation, a comparative format did not differentially influence attitudes toward the product.

How an information source or endorser influences the persuasion process has been of long-standing interest. Research by Priester and Petty (1995) and Kang and Herr (2006) provide evidence that aspects of message sources can take on different roles in the persuasion process. Priester and Petty (1995) demonstrated that expectations of source trustworthiness can result in greater or lesser elaboration of message content. Similarly, Kang and Herr (2006) demonstrated that when

source attractiveness is related to the nature of the product, attractiveness can serve as an argument but when attractiveness is unrelated to the nature of the product, source attractiveness serves as a peripheral cue.

While other studies can also be interpreted as consistent with the ELM's multiple roles for variables perspective (see Petty & Wegener, 1998), future research showing multiple roles for the same variable in the context of a single study (along with process measures) would be an important and valuable contribution to basic research as well as provide useful advice for practitioners in a wide variety of domains.

CHALLENGES AND CONTROVERSIES

Dual route models support the view that attitude change can take place by direct influences of factors such as emotional reactions (e.g., classical conditioning) as well as automatic influences of variables serving as heuristics or peripheral cues. Importantly, dual route models are "moderated mediation" models (Petty, 1997). In his presidential address to the Society for Consumer Psychology, Martin Fishbein challenged the validity and usefulness of dual route perspectives to attitude change. Fishbein and Middlestadt (1995) state that all attitude change is cognitive and is accounted for by the expectancy-value theories perspectives on attitude change processes and that studies that purport to show otherwise are methodologically flawed. Fishbein and Middlestadt's provocative address and subsequent article resulted in a series of responses appearing in the *Journal of Consumer Psychology* (Herr, 1995; Haugtvedt, 1997; Priester & Fleming, 1997; Miniard & Barone, 1997; Schwarz, 1997). Fishbein and Middlestadt (1997) provide a response to the commentaries. Chapters 17 and 20 of this volume offer perspectives that also address the views of Fishbein and Middlestadt.

Fishbein's perspective can be characterized as a single process model. In a similar manner, Kruglanski and his colleagues (1999, 2006a, 2006b) use his Lay Epistemic Theory to reinterpret many areas related to social psychology including attitude change and persuasion. Kruglanski and colleagues (Kruglanski & Thompson, 1999, Kruglanski et al., 2006a, Kruglanski, Erb, Pierro, Mannetti, & Chun, 2006b) believe that their "unimodel" provides a more parsimonious approach than dual process models such as the ELM and HSM. Kruglanski's view has stimulated a great deal of commentary and debate. Responses by Petty, Wheeler, and Bizer (1999) and Petty and Brinol (2006) address Kruglanski's misinterpretation of the ELM. Wyer (2006) and Pryor and Reeder (2006) also provide critiques of the unimodel.

CURRENT RESEARCH DIRECTIONS

Research on the attitude construct, attitude structure, and attitude change continues to address classic questions raised in the early literature. An examination of recent literatures in psychology and other disciplines clearly shows reciprocal influences of theories and research methods from diverse areas. As the range of chapters in this *Handbook* illustrates, many similar predictions and process level explanations can be derived from seemingly different areas of inquiry. In this section, we provide a brief overview of evolving areas of research in consumer and social psychology as they relate to attitudes and attitude change processes.

Attitude Structure

Inherent in the discussion of attitudes and attitude change are issues associated with attitude structure and properties of attitudes. An overview and detailed discussion of attitude structure con-

cepts, as well as the larger context of various debates and research topics can be found in Fabrigar, Macdonald, and Wegener (2005) as well as other chapters in *The Handbook of Attitudes* (Albaricín, Johnson, & Zanna, 2005). Attitude structure properties include the accessibility of attitudes (e.g., Fazio, Sanbonmatsu, Powell, & Kardes, 1986); the affective, cognitive and behavioral bases of attitudes (e.g., Ostrom, 1969); the functional nature of attitudes (e.g., Katz & Stotland, 1959); working knowledge (e.g., Wood, Rhodes, & Biek, 1995); complexity of knowledge (e.g., Scott, 1969; Tetlock, 1989); attitudinal ambivalence (e.g., Priester & Petty, 1996; Priester & Petty, 2001; Priester, Petty, & Park, in press; Thompson, Zanna, & Griffin, 1995); attitude systems (e.g., Judd, Drake, Downing, & Krosnick, 1991); and dual attitude structure (e.g., Wilson, Lindsey, & Schooler, 2000; Petty, Tormala, Brinol, & Jarvis, 2006).

Much of the work on attitude change and persuasion assumes that attitudes exist in memory and that aspects of the attitudes as well as situational factors make it more or less likely that persons will use the pre-existing evaluations. Some researchers and theorists (e.g., Schwarz & Bohner, 2001) challenge this view. While there are numerous sources to review concerning the debates concerning a constructivist view of attitudes, a set of papers in the *Journal of Consumer Research* highlights many issues for consideration and clarification in future work related to the attitude construct and persuasion process in consumer psychology (e.g., Cohen & Reed, 2006a, 2006b; Johar, Maheshwaran, & Perrachio, 2006; Park & MacInnis, 2006; Petty, 2006; Schwarz, 2006).

Metacognitive Processes

Although understanding thought processes is a long-standing issue of interest in psychology (e.g., James 1890), research and theory development on the topic of social cognition (e.g., Fiske & Taylor, 1991) has highlighted the importance of thought processes in specific domains such as social judgment (cf., Petty, Brinol, Tormala, & Wegener, in press). Recent theoretical frameworks have focused on the issue of “thoughts about thoughts.” As noted in our earlier discussion of attitude change processes, the role of primary thoughts in attitude change processes could range from elaborate, effortful, and complex or simple, less effortful inferences. Petty and his colleagues have begun to systematically examine how aspects of an individual’s thoughts about thoughts underlying personal attitudes influence issues such as attitude confidence and certainty and the role of such thoughts in resistance to attitude change (cf., Petty, 2006). This metacognitive perspective has led to new insights regarding various phenomena associated with attitude change and persuasion. For example, Tormala and Petty (2002) demonstrated that when participants perceive themselves resisting persuasion they can become more certain of their initial attitudes. In a subsequent study, Tormala and Petty (2004) showed that participants became more certain of their attitudes only when they resisted a message that came from a high expertise source. They were also able to show that the correspondence between attitudes and behavioral intentions was higher in conditions where attitudes were held with greater certainty.

Another interesting area of metacognitive guided insights comes from research on the ease of retrieval. Ease of retrieval research has generally shown that how easy something comes to mind is an indicator of the validity of the information. Tormala, Brinol, and Petty (2002) suggested that ease of retrieval effects can be mediated by feelings of confidence or validity associated with the particular thoughts. Building on this research, Brinol, Petty, and Tormala (2006) found that the typical effect was replicated when they told participants that ease of retrieval was a sign of positive mental functioning. Interestingly, the typical finding was reversed when they told participants that ease of retrieval was a sign of negative mental functioning.

Petty, Tormala, Brinol, and Wegener (in press) discuss their metacognitive view of attitudes and social judgment and they provide a set of postulates to help provide an organizational framework for knowledge in this area. Campbell and Kirmani (chapter 21, this volume) provide examples of metacognitive processes based on Friestad and Wright's (1995) Persuasion Knowledge Model. We anticipate much more work will be done on the topic of metacognition in consumer psychology related to attitudes and attitude change as well as other areas in the coming years. Research on this topic may also be a fruitful point for collaboration between behavioral decision researchers and researchers interested in persuasion processes.

IMPLICIT AND EXPLICIT ATTITUDES AND ATTITUDE CHANGE PROCESSES

The topics of implicit attitudes and implicit social cognition are discussed in detail by Perkins et al. (chapter 17, this volume). The topic is also addressed by Vargas (chapter 18, this volume) and Fazio and Olson (2003). Systematic research on the nature and influence of implicit attitude change processes are in early stages of development. Related to the attitude strength focus in part of this chapter, findings in a recent study by Karpinski, Steinman, and Hilton (2005) are of particular interest. Using Fazio's MODE (Jones & Fazio, this volume) model as a theoretical guide, Karpinski and Steinman (2005) found that attitude importance served as a moderator of the relationship between Implicit Association Test (IAT) scores and explicit measures of attitudes. Stronger relationships between IAT scores and explicit attitudes were observed under high attitude importance for the topics such as presidential politics as well as attitudes toward consumer products such as Coke and Pepsi. Explicit attitudes were better predictors of deliberative behaviors than were IAT scores for both sets of topics. In their third study, the authors provided data that supported the hypothesis that increased elaboration was a mechanism by which attitude importance moderated IAT-explicit attitude correlations.

Rydell and McConnell (2006) offer a "systems of reasoning analysis" of implicit and explicit attitude change. They suggest that explicit attitude change is based on a fast learning system requiring some degree of cognitive resources. Implicit attitude change, they suggest, is based on an associative system that is characterized by slower processes of repeated pairings between an attitude object and evaluations. In series of five studies, they show that explicit attitudes are affected by explicit processing goals and were better predictors of deliberative behavioral intentions. In contrast, implicit attitudes were unaffected by explicit processing goals and were better predictors of spontaneous behaviors.

The research findings by Karpinski and Steinman (2005) and Rydell and McConnell (2006) seem to be in conflict. Are the same underlying mechanisms operative in both situations? Are implicit attitudes based on a different cognitive system or process or are they simply efficient storage and access mechanism for attitudes that were initially developed in different ways? In addition, what happens in the attitude change process? Do attitudes that are formed and changed via explicit processes eventually become implicit attitudes? If so, what speeds up or slows down these processes? Does having greater agreement between explicit and implicit attitudes lead to greater satisfaction with a product or service? Why are the attitudes of subgroups influenced by both subtle and powerful factors in the assessment situation?

Research on the relationship between implicit and explicit attitudes and attitude change processes is needed to understand how the properties and processes associated with explicit attitude change compare with properties and processes associated with implicit attitude change. We anticipate that much of this research will be conducted by consumer psychologists. Similar to other areas of research, we anticipate that the initial confusion will lead to the development of overarching

frameworks that help researchers and practitioners better able to predict when particular processes are more or less likely to occur. In the remainder of this chapter, we review some of the newest theoretical formulations and perspectives that have been offered in attempts to reconcile and integrate past theory and research findings with newer perspectives in cognitive psychology.

Future Directions

Cohen and Reed (2006a) offer the Multiple Pathway Anchoring and Adjustment model (MPAA). The MPPA, based on traditional theories of attitudes, attempts to account for implicit and explicit attitude change as well as factors that influence attitude activation and expression. Schwarz and Bohner (2001) argue that knowledge structures are used to construct new evaluations as demanded by situations. In this constructivist view, attitudes do not exist as stored evaluations in memory. Rather, components of knowledge that influence evaluation come together when needed for evaluative expression and decision making (e.g., Schwarz & Bohner, 2001). In contrast to the constructivist view, Cohen and Reed (2006) argue that many attitudes undergo an anchoring and adjustment process at the point of expression or decision making. Using various research findings and theoretical frameworks from attitude strength and accessibility/diagnosticity perspectives, Cohen and Reed discuss the possibility that attitudes have characteristics of representational and functional sufficiency. Representational sufficiency of an attitude relates to the existence of a clear and understandable position toward a given attitude object. Functional sufficiency focuses on the idea as to whether or not the attitude is a good basis for a particular behavior—providing a mechanism for connecting attitudes to behavior (c.f., Fabrigar, Petty, Smith, & Crites, 2006). In cases when an attitude does not provide a good basis for behavior, Cohen and Reed (2006) suggest that other processes may come into play. Another important consideration according to the MPAA is the idea that attitude research needs to give greater consideration of role attitudes play in self-identity (cf., Shavitt, 1990; Shavitt & Nelson, 2000).

In recent years, discussions have focused on the possibility of dual attitudes (Wilson, Lindsey, & Schooler, 2000). In this view, some responses to an attitude object may be based on implicit attitudes; whereas others are based on explicit attitudes. In some cases, an automatic override mechanism is utilized. Cohen and Reed (2006) suggest that multiple attitudes may exist for the same attitude object. They suggest that the multiple attitudes may exist independently. In their view, some attitudes are more appropriate for some situations than others.

The Associative-Propositional Model (Gawronski & Bodenhausen, 2006, in press) focuses on how sometimes automatic associative processes (e.g., automatic affective reactions) influence attitude formation and change, whereas in other situations, a deliberate propositional process (e.g., evaluations based on syllogistic inferences) occur in attitude formation and change. The former refers to implicit processes which might be assessed with the IAT or evaluative priming (see chapter 16, this volume), whereas the latter refers to explicit processes which might be assessed with the semantic differential. Similar to Deutsch and Strack's (2006a, 2006b) RIM model discussion of the reflective and impulsive components, both of these processes are assumed to be independent (cf., Sherman's, 2006a; 2006b Quad model).

In yet another model related to the ideas noted above, Petty's metacognitive view of attitudes (MCM; e.g., Petty, 2006; Petty, Brinol, Tormala, & Wegener, in press; Petty, Tormala, Brinol, & Jarvis, 2006) includes the PAST Model. In the Past Attitudes are Still There (PAST) model, the old attitude is tagged with a label indicating that it is held with lessened confidence, however, the old attitude still exists and can be activated in certain situations. According to the PAST model, two attitudes relevant to the same object can be activated at the same time. In some cases, the activated

attitudes might have different valences. (cf., Cacioppo, Gardner, & Berntson, 1997). From the perspective of the MCM, persons will sometimes actively assess the validity of their reactions to an attitude object, and at other times this process will be more automatic. These assessment processes will sometimes cause a tension or ambivalence in the attitudes and may change the nature of the attitude representations.

SUMMARY

As we stated at the outset of this final discussion, much of the research in the area of the relationship between implicit and explicit attitudes and attitude change processes is in the early stages of development. The principles of attitude change processes that have been researched and supported in the past thirty years are likely to stand the test of time, but we look forward to new insights gained about the way in which implicit attitudes are formed and changed. Advances in the past thirty years have in part been made possible by programmatic approaches to research in which initial phenomena are reliably created in standardized laboratory settings. Systematic manipulation of variables designed to assess underlying processes the boundary conditions have built on the foundation of the early research. We hope that the work on the new areas follows the trend of programmatic approaches to the research.

Associative Strength and Consumer Choice Behavior

CHRISTOPHER R. M. JONES

RUSSELL H. FAZIO

Ohio State University

INTRODUCTION

The practice of advertising is predicated on the assumption that consumer choice behavior is at least partially determined by representations of the product or brand in memory. Rather than entering a choice situation as a “blank slate” and assessing alternatives completely on-the-spot, individuals virtually always have some knowledge of the type or category of product in question and often about specific brands as well. According to associative network theories of cognition (e.g., Anderson & Bower, 1973), these representations are not isolated but linked in memory by connections that vary in strength. This chapter will consider how concepts like brands and categories of products can be related to other representations in memory and the implications for consumer behavior.

We begin with the assumption that these consumer-related concepts can be uniquely represented in memory and associated to varying degrees with other mental representations. This variation, the strength of the association between two representations, determines the likelihood that activating one concept will result in the activation of the associated concept. Obviously, the nature of the associates of, for example, the representation of a brand will largely determine how an individual thinks about that brand and whether they might choose to purchase it. Further, not all associations are created equal. A representation strongly associated with a brand is more likely than a representation weakly associated with a brand to ultimately influence behavior. Predicting consumer choice thus entails having some idea about both the content of associated representations and on the strength of those associations.

Many different kinds of associations in memory may prove relevant to consumer behavior. A brand, for instance, might be associated with usage situations, particular attributes, previous experiences, and so on. We will focus on two kinds of associated representation: *attitudes*, which can be conceptualized as associations between an object and a summary evaluation of that object, and *category-exemplar* associations, associations between an object and a superordinate classification. The goal of this chapter is to describe some differences and commonalities between these two types of associations, both of which we believe to be important for understanding consumer choice

behavior. The chapter will present some broad guidelines for identifying situations and product classes for which each type of association is likely to be particularly relevant. We will first focus on the determinants and consequences of attitudinal associative strength. We then will turn to category-exemplar associations, and then finally we will discuss some contextual factors that moderate the role of associative strength in consumer choice situations.

ATTITUDES: OBJECT-EVALUATION ASSOCIATIONS

Attitudes can be viewed as associations in memory between an object and one's summary evaluation of that object (Fazio, Chen, McDonel, & Sherman, 1982). When individuals encounter or consider an attitude object, the associated evaluation can be activated. The likelihood that an evaluation is activated contingently by the attitude object is the attitude's *accessibility*, and it is determined by the strength of the association between the object and evaluation. Since the proposal of this theoretical perspective, considerable research has examined the consequences, determinants, and correlates of attitude accessibility and its role in the attitude-to-behavior process (see Fazio, 1995, for a review). This section will review these findings with attention to the implications for how attitudes function in object-appraisal and decision-making processes of interest to consumer psychology.

Before proceeding, it will be useful to clarify what is intended when describing attitudes as object-evaluation associations in memory that vary in strength. Both object and evaluation are meant broadly. Individuals may not only store evaluations of physical objects, but also of concepts of all levels of abstraction. These evaluations associated with objects have various bases that range from "hot" affective responses to "cold" analytical beliefs concerning attributes of the object. Regardless of the precise nature of the object and evaluation, the strength of the association between the two will influence the likelihood of its use. This structural approach to attitude strength and to attitudes in general has the advantage of operating at an information processing level of analysis, allowing for specificity in the treatment of the concept and integration thereof into broader models of cognition and behavior (e.g., Fazio, 1990; Herr & Fazio, 1993).

Accessibility

The crux of the conceptualization of attitudes as object-evaluation associations is that the strength of this association influences attitude accessibility, the likelihood that the attitude will be activated from memory automatically when the object is encountered. Here, the term "automatic" refers to the attitude being activated "whenever a given set of external initiating stimuli are present, regardless of a subject's attempt to ignore or bypass the distraction" (Shiffrin & Dumais, 1981, p. 117). This begs the question of how associations attain such strength. According to associative network theories of mental representation, associations in memory will be strengthened to the extent that the representations they link are experienced or thought about together; this strength changes only slowly over time (Smith & Queller, 2001). Attitude accessibility can be measured by the latency of response to a direct attitudinal inquiry. Relatively high accessibility may be chronic, reflecting high associative strength, or it may be temporarily enhanced by recency of use (Higgins, 1996).

Empirical support regarding the automatic activation of attitudes was gathered using priming procedures (Fazio, Sanbonmatsu, Powell, & Kardes, 1986). The evidence concerns the effect of semantic primes on the latency with which individuals are able to identify the connotation of target adjectives (e.g., attractive, disgusting) as positive or negative. These primes were positive or negative words selected idiosyncratically for each participant. For each participant, attitudes towards the

objects were categorized as accessible or inaccessible according to the latency of response required to evaluate them. Priming with these items, which were presented to participants as distracting “memory words,” facilitated performance in the adjective connotation task when the valence of the primed object was the same as the valence of the target adjective. That is, responding was faster. On the other hand, when the valence of the prime and target were incongruent, it took longer to identify the target adjective as positive or negative. So, participants were able to classify a positive adjective more quickly when it was preceded by a positively valued object. Importantly, the facilitation and inhibition effects of the primes were more pronounced for objects towards which participants held accessible attitudes.

Similar automatic attitude activation has been demonstrated in research employing brand names as primes (Sanbonmatsu & Fazio, 1986). Accessible attitudes towards brand names influenced how quickly individuals could categorize the target adjectives that followed them as positive or negative.

A notable characteristic of the priming procedure is that accessible attitudes towards the prime words influenced evaluative categorization even though participants were aware that the prime itself was irrelevant to their goals in the task, providing preliminary evidence that the influence of the primes was spontaneous and uncontrollable. Further evidence of the validity of automatic attitude activation is that it also occurs when participants are engaged in a task that is not dependent on any evaluative intent (e.g., Bargh, Chaiken, Raymond, & Hymes, 1996).

The findings regarding the moderating role of associative strength on automatic attitude activation relate to an important conceptual distinction offered by Converse (1970). Noting that a person may respond to an evaluative item on a survey even though that person had never previously encountered or considered the item’s referent, Converse (1970) distinguished between attitudes and nonattitudes. Based on the finding that attitude accessibility varies as a function of associative strength, it has been suggested that the distinction between attitudes and nonattitudes may be more usefully considered a continuum (Fazio, Sanbonmatsu, Powell, & Kardes, 1986). At the non-attitude end of the continuum is the case in which no appropriate a priori evaluation is available in memory and evaluative assessment must occur in an on-line fashion. Approaching the upper end of the continuum, well-learned object-evaluation associations are increasingly capable of being activated automatically from memory. This does not mean that only highly accessible attitudes are available in memory. Attitudes that are low in accessibility may also be activated, but this is more likely to require motivated efforts to retrieve information about the attitude-object.

The potential for automatic activation provides much of the functional value of attitudes. Accessible attitudes can be activated instantly upon encountering an attitude-object and help individuals understand and react to the world around them. The basic value of attitudes is this object-appraisal function (Smith, Bruner, & White, 1956) and automatic activation allows the rapid initiation of approach or avoidance behavior based on these object-appraisals. The following sections will discuss the consequences of attitude accessibility, which determines the functional role of attitudes in guiding thought and behavior.

Manipulating Associative Strength

A number of manipulations have been used to increase the strength of the association between attitude-objects and evaluations (thus increasing attitude accessibility) in the laboratory. Always, participants are one way or another induced to note and rehearse their attitudes by repeatedly expressing them. For instance, this has been achieved by requesting that participants copy their attitudinal ratings onto multiple forms (Fazio et al., 1982, Experiment 3). Other studies (e.g., Powell

& Fazio, 1984) varied the number of times that a particular attitude-object appeared on a questionnaire, in each instance followed by a different (but always evaluative) semantic differential scale. Another variation of this manipulation has the advantage of distinguishing the effects of attitude accessibility from mere object accessibility (e.g., Fazio et al., 1986, Experiment 3; Roskos-Ewoldsen & Fazio, 1992, Experiment 2). In these experiments, each attitude-object was presented an equivalent number of times, but how often the attitude-object was paired with an evaluative question versus some control question (e.g., “Is this object animate or inanimate?”) varied. Increasing attitudinal associative strength through repeated expression increases automatic attitude activation, measured by the extent to which that attitude-object facilitates the evaluative categorization of items of congruent valence and inhibits the evaluative categorization of items of incongruent valence (Fazio et al., 1986). As we describe the ways in which attitudes ultimately exert an influence on behavior in the following sections, it should be remembered that such effects should only be expected when object-evaluation associations are sufficiently strong, either due to a manipulation of associative strength or the pre-existing strength of associations held by individuals.

CONSEQUENCES OF ATTITUDE ACCESSIBILITY

An interaction with a physical object often begins with a perception and ends in behavior. We will first review evidence suggesting that attitudes can bias individuals’ basic perceptions of visual stimuli. In subsequent sections, we will explore other consequences of the associative strength of attitudes—ones that serve as further mechanisms through which attitudes ultimately shape behavior.

Perception

Higher-order cognitive and motivational processes can influence perception in a top-down fashion. For example, it has been demonstrated that individuals perceive a briefly presented ambiguous figure (it could be construed as either the letter “B” or the number “13”) in the manner consistent with their desired outcome (Balcetis & Dunning, 2006). Participants were informed that a number or letter would appear on a computer screen, indicating into which experimental condition they would be assigned. Participants were more likely to perceive the stimulus in a way that would indicate that they would be in the condition requiring that they drink orange juice rather than a disgusting, viscous “health drink.” This type of motivation, described by Balcetis and Dunning as “wishful thinking” extends previous research documenting similar perceptual effects caused by motivation from biological drives. For example, Changizi and Hall (2001) found that when individuals were thirsty, they displayed a greater tendency to perceive a concept associated with water, transparency, in ambiguous visual stimuli varying in opacity.

Research by Powell and Fazio (summarized in Fazio, Roskos-Ewoldsen, & Powell, 1994) examined the influence of attitudinal biases on perception in an informationally sparse visual environment. Participants were required to observe a computerized tennis game in which flashes of light appeared in a rectangle divided by a vertical line, representing a tennis court. The flashes of light represented the location of shots landed by either the computer or (supposedly) a confederate who had previously behaved in such a way that he/she would be liked or disliked by the participant. On target trials, flashes of light appeared within 5 pixels of the end line, making the participants’ task, judging whether the shot landed “in” or “out,” difficult. Despite being informed that their judgments (indicated with a key press) were solicited only to test the quality of the game’s visual display and that the computer would accurately judge and tally the score, participants displayed patterns

of errors that were influenced by their liking of the confederate. Participants who had been led to like the confederate called more balls hit by the confederate “in” when they were truly “out” and balls hit by the computer “out” when they were truly “in” than errors which would have been in the computer’s favor. The opposite pattern of results was observed when participants had been led to dislike the confederate.

Attention

An important aspect of the influence of associative strength on basic perceptual processes is the potential for objects associated with highly accessible attitudes to attract visual attention when the object enters the visual field. Roskos-Ewoldsen and Fazio (1992) assessed recall for stimulus items presented briefly in groups of six in a circular visual array. Participants were more likely to notice and report objects for which they held more accessible attitudes. This was the case both when attitude accessibility had been previously measured by latency of response and when it was manipulated through attitude rehearsal. In another experiment in the series, participants noticed the more attitude-evoking objects incidentally, i.e., even when their task was to categorize a stimulus that appeared in the center of the visual array of objects as either a number or a letter. In a final experiment, performance on a visual search task was shown to be disrupted by the presence of more attitude-evoking objects as distractors. Attitude accessibility predicted the extent to which these distractors interfered with performance on the visual search task. Thus, the influence of attitude accessibility on selective attention appears to be automatic not only in that it is spontaneous, but also in that it occurs regardless of intentional efforts to ignore the attitude-object.

Roskos-Ewoldsen and Fazio (1992) argued that attitudes provide an adaptive, orienting function towards objects that have hedonic value, allowing them to be rapidly approached or avoided. These findings may be of particular relevance to consumer psychologists. In any environment, multiple stimuli are likely to be present that may attract an individual’s attention. Indeed, in environments such as supermarkets, many objects are specifically designed to attract attention and are intended to compete in this respect with one another. One strategy to ensure that a product draws attention is through manipulating properties of the object itself, usually by carefully designing its appearance. Another approach is to depend on the accessibility of consumers’ attitudes towards the brand to guide attention. Sometimes, it may be easier or more effective to influence consumers’ mental representation of the product than to enhance the relative attention-drawing capacity of the object itself.

Categorization

All objects are multiply categorizable and the particular category or categories activated depend not only on properties of the object, but also on those of the observer. Another consequence of the associative strength of an attitude is its capacity to determine which of multiple suitable categories is actually applied to the object (Smith, Fazio, & Cejka, 1996). For instance, at any moment in time a given individual might construe a cup of yogurt as a “snack” or as a “dairy product.” For a person with lactose-intolerance, the category dairy product is likely to be strongly associated with a negative evaluation. This associative strength makes the category more attitude-evoking, more likely to attract attention, and, hence, more likely to dominate construal of the yogurt. That is, the individual is more likely to categorize yogurt as a dairy product than a snack. Across a series of experiments, Smith et al. (1996) obtained empirical support for the notion that highly accessible attitudes towards categories determine which categories will be preferentially applied to multiply

categorizable stimuli. An attitude rehearsal manipulation increased the accessibility of attitudes toward one of two potential categorizations for each item in a series of objects. When these objects were later presented as a cue, the category for which attitudes had been rendered more accessible was more likely to be evoked. In addition, individuals could more quickly verify that the category applied to the object. Thus, accessible attitudes shape basic categorization processes and facilitate construals that are hedonically meaningful.

Information Processing

Relatedly, yet another well-known consequence of attitudes is their potential to shape the manner in which individuals interpret information. As a function of their personal biases, individuals may view and describe the same event in radically different ways (e.g., Hastorf & Cantril, 1954). In a classic experiment, Lord, Ross, and Lepper (1979) found that individuals who held strong opinions toward the death penalty examined relevant empirical evidence in a biased manner. College students who either supported or opposed capital punishment were exposed to two fabricated studies, one that seemingly provided evidence supporting the efficacy of the death penalty as a deterrent to crime and one that denied it. Participants rated not the conclusions but the actual methodology of the studies as being more valid when the study reached conclusions consistent with their own attitudes. Participants actually endorsed their initial opinions more strongly after reading the conflicting accounts, even though the quality of the messages themselves was essentially equal.

Houston and Fazio (1989) examined the influence of attitude accessibility on such information processing. Because the participants in the research by Lord and colleagues (1979) were selected on the basis of their strong pre-existing attitudes toward the topic, Houston and Fazio reasoned that these participants likely had highly accessible attitudes toward capital punishment and that the biased processing effect might be less general and not occur for participants who did not have such accessible attitudes—an attitude will not bias processing if it is not activated. Attitude accessibility was measured in one study via latency of response to a direct attitudinal query and experimentally manipulated via repeated attitudinal expression in another. In both cases, the strength of the object-evaluation association predicted the degree of correspondence between attitudes toward capital punishment and ratings of the scientific quality of the studies. The correlations were rather meager among the participants whose attitudes were relatively low in accessibility (r 's < .18), but accounted for much more variance among those with greater attitude accessibility (r 's .44–.58). Attitudes had a much stronger biasing influence as the strength of the object-evaluation association increased.

That accessible attitudes bias the processing of incoming information is consistent with the finding that the impact of a persuasive communication is attenuated when an individual can rapidly retrieve attitudinal beliefs about the message topic from memory (Wood, 1982). For this reason, another consequence of attitudinal associative strength may be stability, insofar as highly accessible attitudes are relatively resistant to change. Holding accessible attitudes towards a product or brand, then, will influence the processing of relevant information. A positive attitude, if activated, can attenuate the impact of all manner of negative information, be it unfavorable nutritional information or a communicated negative reaction from a friend, acquaintance, or even an expert, as suggested by the supposed origin of the capital punishment arguments in the above studies. Of course, negative attitudes, exert a similar biasing influence, suggesting that, for example, advertisers may have great difficulty in modifying highly accessible negative attitudes and that attempts to “re-position” the brand as a new product may be a more successful alternative (Herr & Fazio, 1993).

Ease of Decision Making

Attitudes allow individuals to access stored evaluations from memory based on previous experience with an attitude-object rather than being forced to effortfully generate immediate appraisals of an object on every instance on which it is encountered, a process that is dependent on the availability of cognitive resources and is comparatively slow. For this reason, attitudes should influence the decision making process not only by biasing it, but also by easing it. Research in psychophysiology has established that “patterns of enhanced autonomic, especially cardiovascular, reactivity are associated with psychologically effortful or challenging situations involving decision making and other types of cognitive activities” (Blascovich, Ernst, Tomaka, Kelsey, Salomon, & Fazio, 1993, p. 165). A series of experiments exploited these biological hallmarks of effort to test the hypothesis that accessible attitudes ease decision making by using physiological measures (Blascovich et al., 1993; Fazio, Blascovich, & Driscoll, 1992). Sharing a common paradigm, these experiments required participants to make preference judgments between pairs of abstract paintings under significant time pressure. Before this pairwise preference task, some participants repeatedly reported their liking for each painting while others merely announced the predominant color appearing in each painting, allowing the experimenters to control for the familiarity of the stimuli while manipulating their position on the attitude-nonattitude continuum. When making their pairwise preference decisions, participants in the attitude-rehearsal condition displayed less reactivity on a variety of cardiovascular and skin conductance measures. Accessible attitudes, importantly, reduce the resource-dependence of decision making both cognitively and physically (see Fazio & Powell, 1997, for consideration of the long-term implications of such attitudinal functionality for adjustment and well-being).

The MODE Model

Attitudes are generally of interest because of their potential to guide behavior. However, human behavior is multiply determined, and the specific role of attitudes in provoking behavior has been a subject of some controversy (see Zanna & Fazio, 1982, for a historical review). Much of the research program discussed so far grew out of an investigation of the problem of attitude-behavior consistency. That is, sometimes attitudes have been noted to be very poor predictors of actual behavior (e.g., see LaPiere, 1934, for a famous albeit not methodologically rigorous instance; or Wicker, 1969, for an influential review). There are obvious reasons why this could be the case. As a determinant of behavior, attitudes sometimes compete against impulses derived from individuals' immediate construal of their situation that may dictate a different behavior than would be predicted from an attitude measure. Behavioral norms, for instance, have a moderating influence on attitude-behavior consistency (Ajzen & Fishbein, 1973). Also, as individuals experience the world they encounter actual, unique exemplars of attitude-objects. Deliberative evaluations of these objects in the context in which they appear may bear little resemblance to a stored evaluation of a prototype (Lord & Lepper, 1999; Lord, Lepper, & Mackie, 1984).

The MODE model (Fazio, 1990) of attitude-behavior consistency outlines the general conditions under which object-evaluation associations can be predicted to guide behavior. Attitudes can be activated automatically and influence behavior in a relatively spontaneous manner. By coloring one's appraisal of an object in the immediate situation, attitudes can promote approach or avoidance behavior, even without the individual reflecting upon the behavioral action. However, individuals also may determine a situationally appropriate course of action through thoughtful analysis of its costs and benefits (see Ajzen & Fishbein, 1980). The MODE model postulates that

Motivation and Opportunity are *Determinants* of which mode of evaluative processing, spontaneous or deliberative, is likely to occur in a given situation. First, deliberative processing is contingent on an individual's Motivation to undergo thoughtful reflection regarding a behavioral decision. The MODE model may be viewed as an extension of Kruglanski's (1989) theory of lay epistemology to the question of the attitude-behavior relation. Kruglanski (1989) described general processes and motivating variables relevant to the acquisition of knowledge. When individuals are motivated to avoid reaching an invalid conclusion due to its perceived consequences, they are said to have "fear of invalidity," and are likely to carefully deliberate concerning the relevant judgment or action. Applying these ideas to the attitude-behavior relation, when individuals are motivated by "fear of invalidity" to expend cognitive effort, behavioral decisions (which may or may not appear consistent with one's attitudes) will be reached through effortful deliberation.

While motivational factors may initiate deliberative processing, it must also be considered that even when such deliberation is desirable, it may not always be possible. Thus, Opportunity is the second element of the MODE acronym, because situations will occur in which time pressure or resource depletion precludes the possibility of sufficient cognitive effort. By virtue of their capacity for automatic activation, attitudes may guide behavior by default in these circumstances. In the case of a more spontaneous attitude-behavior relation, accessibility will play a moderating role. Even if motivation and opportunity are lacking, attitudes will only determine behavior if they are activated from memory. If stored attitudes are not retrieved, an individual's behavior must depend on their immediate appraisal of the situation, regardless of any insufficiency in motivation or opportunity for satisfactory deliberation on it.

MODE's acronymic assumption that motivation and opportunity are determinants of processing type has been tested in a laboratory experiment using consumer choice scenarios. Sanbonmatsu and Fazio (1990) presented participants with a series of statements about two department stores that described qualities of the various departments of each. The hypothetical department store "Smith's" was generally presented in favorable terms whereas "Brown's" was generally described in unfavorable ones. Consistent with their instructions to form a general evaluation of the two stores, participants did come to view Smith's much more favorably than Brown's. However, contrary to the general evaluation thus formed, the camera department of each store was described in the opposite fashion—as unfavorable at Smith's but as favorable at Brown's. This resulted in particular attribute information in opposition to the valence of the summary evaluation associated with each store. Later, participants were asked to imagine which store they would prefer to buy a camera from. Choosing Smith's would suggest that participants relied on their attitudes toward the department stores themselves without any further considerations, indicating relatively effortless processing. On the other hand, a choice of Brown's would suggest that participants underwent the deliberative process of retrieving relevant information, comparing specific attribute information, and disregarding the general preference for Smith's relative to Brown's.

The conditions under which the decision was made were manipulated with respect to both the motivation and the opportunity participants would have to deliberate upon it. The opportunity to deliberate was determined by allowing some participants only 15 seconds to decide while others were not subject to time constraints. Crossed with the manipulation of opportunity for deliberation, half of the participants were motivated to make an accurate decision by the expectation that they would later have to justify their choice to other participants and the experimenter, while others would have no reason to perceive their choice as having any repercussions whatsoever. The results conformed to predictions from the MODE model. Participants who were motivated to make an accurate decision and had unlimited time to do so were more likely to make a choice indicative of deliberative processing (choosing the store with the better camera department) than partici-

pants in any of the other three conditions. The latter relied on their general attitudes toward the two stores.

The specific role of attitude accessibility in the MODE model was tested in a field experiment investigating the 1984 presidential election (Fazio & Williams, 1986). Attitude accessibility towards the Republican and Democratic presidential candidates, Ronald Reagan and Walter Mondale, was measured in a large sample of individuals approached at a shopping mall. Latency of response to attitudinal queries regarding each candidate moderated the degree to which those attitudes predicted (1) participants' judgments of the quality of performance by each candidate during a subsequent televised debate, and (2) participants' actual voting behavior several months later. That those with highly accessible attitudes towards the candidates judged the performances in the presidential debates in accordance with those attitudes supports the assertion that one's attitudes can color judgments about complex social stimuli, likely due to the various perceptual, attentional, and biased-processing consequences of attitude function described above. Moreover, such attitudinally-driven biases increase as the strength of the object-evaluation association increases. The finding regarding voting behavior illustrates the persistence of more accessible attitudes over time and, hence, their greater likelihood of influencing subsequent behavior, in this case months later.

The basic finding from the election study supporting the prediction that attitude accessibility moderates the attitude-behavior relation was replicated in the laboratory using consumer products as attitude-objects (Fazio, Powell, & Williams, 1989). Following the usual latency measure of the accessibility of attitudes towards 100 products, participants were given the opportunity to select five products from a set of 10 alternatives that were arranged into two rows of five and presented on a table. Two observed relationships were moderated by attitude accessibility. First, attitude accessibility moderated the consistency between attitudes and the subsequent product selection measure such that attitudes had greater predictive utility when they were more accessible for a given individual. Also, as attitude accessibility increased, the extent to which participants tended to exhibit a preference for products from the first row decreased. This position effect was irrelevant to the quality of the randomly ordered products, and it was less evident when participants possessed accessible attitudes to guide behavior. Yet, among those with less accessible attitudes, the salience afforded a product by virtue of its positioning in the first row increased the likelihood of its being selected. When people lack strong evaluative associations to an object, their immediate appraisals of the object must be constructed as part of the decision process. In such cases, the immediate appraisals are subject to the influence of momentarily salient, and potentially extraneous, considerations.

Implications for Consumer Behavior

Herr and Fazio (1993) have articulated the relevance of the MODE model to the domain of consumer behavior. The model offers a perspective on when and how attitudes towards products are likely to influence consumer behavior (see Herr & Fazio, 1993, for a much fuller description of the approach, as well as additional implications for advertisers). Most centrally, the model serves to highlight that different marketing strategies may be more appropriate for particular classes of products. Decisions regarding "big ticket" items, which are expensive and/or important purchases, are more likely to be executed in a deliberative fashion than routine purchases (Herr & Fazio, 1993). Even an extremely positive, accessible attitude is irrelevant if an individual has reasoned that they cannot afford the product. Moreover, the importance of the decision is likely to lead to additional review and consideration of the available attribute information, instead of reliance on the pre-existing attitude. Accessible attitudes may color the sampling and evaluation of the relevant data.

So, it is not that attitudes are irrelevant. However, fear of invalidity is likely to promote a return to the data—a bottom-up process instead of a top-down, attitudinally driven process.

In the case of routine purchases, on the other hand, behavior is more likely to be determined by spontaneous processes resulting from automatic attitude activation. With such minor purchases, the potential for normative concerns or fear of invalidity is reduced. The multiple consequences of attitude accessibility and its moderating role in the attitude-behavior relation suggest that, especially with respect to routinely purchased products, attitude accessibility is a variable that marketers have a vested interest in fostering, presuming that the product is good and attitudes are generally positive. Hence, we now turn to what is known about the determinants of associative strength and specific strategies for strengthening object-evaluation associations through advertising.

DETERMINANTS OF ASSOCIATIVE STRENGTH

Rehearsal

As seen in the research on attitude accessibility, the strength of object-evaluation associations can be increased through repetition. Repetition refers to any instance in which the attitude object and the evaluation co-occur, whether solely in one's mind or in the environment. One of the basic assumptions of associative network theories in cognition is that links are strengthened to the extent the objects they link are experienced or thought about together and that strength changes only slowly over time (Smith & Queller, 2001). Noting these co-occurrences may function as trials of associative learning whether the attitude-object is actually present and being evaluated or not. Repetitions may not only take the form of passive observation of co-occurrences, but also may involve actively relating the associated concepts. Repeatedly rehearsing an attitude by expressing it seems to be particularly effective in increasing attitude accessibility, though initial rehearsals will increase attitude accessibility more than subsequent ones when they occur within a short span of time (Powell & Fazio, 1984).

Repetitions of advertisements or other product-related messages obviously have the potential to increase associative strength. Indeed, Berger and Mitchell (1989) found that although four repetitions of an entire advertisement did not enhance the favorability of participants' attitudes toward the target products relative to one presentation of the ad, four exposures did increase the likelihood that their brand selections would be consistent with those attitudes. Presumably, the multiple exposures functioned as instances of attitude rehearsal, which enhanced attitude accessibility and, hence, the likelihood of attitudinally-congruent subsequent behavior.

Evaluative Conditioning

Repeated attitudinal expression involves an individual's noting and rehearsing object-evaluation associations. However, as implied earlier, more passive processes also may promote the development of relevant associations in memory. Mere co-occurrence can be consequential. When two objects are experienced together, a cognitive association between the two will form or strengthen. In addition to strengthening object-object associations, mere co-occurrence may affect other associations. Sometimes when two objects are experienced in conjunction an object-evaluation association of one object becomes closer in valence to that of the other, even in the absence of a causal or otherwise meaningful relationship between the two that would explain and justify such changes in attitude. This phenomenon has been termed "evaluative conditioning" (EC) and is believed to be a distinct form of Pavlovian conditioning. Hence, researchers in this domain have adopted the terminology of classical conditioning research.

According to evaluative learning theory (De Houwer, Thomas, & Baeyens, 2001), the mere spatio-temporal co-occurrence of a positively or negatively valenced unconditioned stimulus (US) and a relatively neutral conditioned stimulus (CS) is sufficient to elicit an affective transfer from the US to the CS. For example, in the implicit learning procedure developed by Olson and Fazio (2001), participants are presented with a rapid, non-rhythmic stream of images on a computer screen. Participants are instructed to attend for particular target cartoons within this stream of images and to respond to them with a button-press. Embedded at intervals within this stream of images are CS-US pairs composed of a different type of relatively neutral cartoon and a moderately positive or negative word or image. One cartoon is paired with positive words or images a total of 20 times, and another is paired with negative words or images 20 times. Olson and Fazio (2001) found that on both an implicit and an explicit attitude measure, participants expressed greater liking for the cartoon that had appeared with positive stimuli than for the cartoon that appeared with negative stimuli, even though these participants did not demonstrate awareness of the CS-US contingencies on a subsequent recall task. Merely presenting the pairs contiguously while participants performed an unrelated task influenced individuals' attitudes toward the CS.

EC is of obvious interest to advertisers and marketers as a method of creating and strengthening positive attitudes. Some of its characteristics serve to further heighten its utility. In addition to potentially occurring without an individual's explicit awareness, EC is a notable attitude-forming process because its effects are more resistant to extinction than signal or expectancy-learning forms of Pavlovian conditioning (Baeyens, Crombez, Van den Bergh, & Eelen, 1988). Presenting the CS without the US after an *evaluative* conditioning procedure does not generally result in "extinction." That is, the attitude towards the object typically does not revert to its prior valence. Another characteristic suggestive of its practical utility is that some studies have successfully demonstrated evaluative conditioning with few conditioning trials, though increasing the number of pairings generally increases evaluative conditioning (De Houwer, Thomas, & Baeyens, 2001). Evaluative conditioning can also occur subliminally (see Dijksterhuis, Aarts, & Smith, 2005, for implications for practical, commercial, and political usage). Dijksterhuis (2004) demonstrated the procedural flexibility of subliminal EC in a series of experiments testing whether implicitly-measured self-esteem could be enhanced by presenting self-related words with positive nouns and adjectives. Such enhancement was obtained not only when the self-related words were presented subliminally (Experiments 1–2), but also when both the CS and US were presented subliminally (Experiments 3–5b). Finally, EC effects can be mediated both by a direct transfer of affect from the US to the CS, or they can be cognitively mediated when the US causes the formation of inferential beliefs about the CS (Kim, Allen, & Kardes, 1996; Kim, Lim, & Bhargava, 1998). The latter cognitive route, however, appears more dependent upon conditions of high involvement and individual need for cognition, as well as upon the awareness of CS-US contingencies (Priluck & Till, 2004).

Some EC research has been conducted in the domain of consumer psychology, though much further research will be necessary to fully explore its role in the formation of attitudes toward brands and products and its potential as a tool for influencing them. The earliest work in consumer psychology related to EC described an associative transfer called "affect referral" as an antecedent of consumer purchases (e.g., Wright, 1975). Shimp and colleagues have most thoroughly examined the role of associative learning in an advertising/consumer behavior context. Gresham and Shimp (1985) attempted to evaluate a classical-conditioning model of advertising by treating affectively valenced commercials as US. Results were mixed. Responses to only 3 of 10 advertisements provided support for the hypothesis that attitudes toward the advertisement would affect attitudes toward the product. Using hypothetical brand names as CS and pleasant images of natural scenes as

US, Stuart, Shimp, and Engle (1987) were more successful in demonstrating a robust conditioning effect on consumer attitudes and replicated some well-known effects in the conditioning literature (e.g., that forward conditioning is superior to backward conditioning), in the consumer domain. A series of 21 experiments tested the effectiveness of evaluative conditioning for various brands of cola (Shimp, Stuart, & Engle, 1991). This research supplied further evidence for EC in the consumer domain and identified a noteworthy moderator. Evidence for EC was only obtained for brands low and moderate in familiarity (see also Cacioppo, Marshall-Goodell, Tassinari, & Petty, 1992).

Another moderator of EC of practical interest is mood. Theories of mood agree that happy moods tend to elicit top-down, concept-driven information processing while sad moods elicit bottom-up, stimulus-driven processing (Forgas, 2002; Schwarz & Clore, 2003). This suggests that sad moods might induce modes of information processing that tend to result in stronger cognitive associations between objects that enter individuals' perceptual fields. The finding that sad moods increase implicit covariation detection (Braverman, 2005), provides some evidence for this hypothesis. Walther and Grigoriadis (2004) found that individuals in sad moods showed greater evidence of both positive and negative evaluative conditioning for consumer attitudes. In their experiment, liked and disliked faces presented with the CS (various images of shoes) had a greater influence on attitudes after watching a sad film clip. More research would also be useful to identify further moderators that determine when evaluative conditioning will prove effective in influencing attitudes towards what products.

PERCEIVED DIAGNOSTICITY

The strength of object-evaluation associations has been found to be influenced by factors in addition to rehearsal and co-occurrence. The perceived diagnosticity of the information on which the attitude is based also plays a role. Attitudinal evaluations may be based on a variety of sources including the emotional reactions evoked by the object, beliefs about the object's attributes and significance, and prior behavior towards that object. Fazio (1995) argued that individuals are sensitive to attitudinal diagnosticity, the perception of the evidentiary base upon which an evaluation is relying, and may view some classes of information as more reliable than other classes of information. As a consequence of individuals' tendency to view particular classes of information as especially diagnostic of their attitudes, individuals may be more likely to note them and to form stronger object-evaluations.

Attitudes are perceived as more diagnostic if they are based on one's own direct experience with the attitude object. Consequently, such attitudes tend to be more accessible from memory (Fazio et al., 1982; Fazio, Powell, & Herr, 1983) and more likely to influence subsequent behavior (see Fazio & Zanna, 1981, for a review). Similar effects of direct experience have been observed in the consumer domain. Smith and Swinyard (1983) found that attitudes towards various snack foods were more consistent with behavior when they were based on a product trial (direct experience) rather than advertising (see Wu & Shaffer, 1987; Berger & Mitchell, 1989, for related findings).

A reason attitudes based on first-hand experience are perceived as diagnostic derives from Bem's self-perception theory. One's own freely chosen behavior is viewed as diagnostic of one's internal states (Bem, 1972). Fazio, Herr, and Olney (1982) found that inducing individuals to recall voluntary behaviors relevant to a given attitude domain increased the strength of the object-evaluation association more so than having individuals review the same class of behaviors in circumstances in which the behavior occurred under coercion.

Emotional reactions to an object also may be viewed as especially diagnostic of one's attitudes toward the object. One's emotional experiences are very much one's own, and, hence, thought to be revealing. Some relevant evidence is provided by Fazio, Zanna, and Cooper (1978), who presented participants with video clips of an actor working on various novel intellectual puzzles. Participants were instructed either to "just listen and watch carefully" or to "imagine how you would feel if you were working the examples." Focusing on the feelings that the puzzles generated led to greater correspondence between the attitudes that participants developed and their behavior during a subsequent "free play" period. In contrast, an extensive research program by Wilson and his colleagues has demonstrated that analyzing the reasons (cognitive bases) for one's attitudes, especially in domains in which it is difficult to verbalize the basis for liking or disliking an object, can weaken attitude-behavior correspondence. Focusing on the presumed reasons underlying one's attitudes can lead to a momentary emphasis on salient and easily verbalizable features that do not necessarily correspond to the factors that determine behavior, or if they do, that determine post-choice satisfaction (Wilson et al., 1989, 1993).

This is not to say that analytical thought cannot provide a useful and valid basis for attitudes. In domains not marked by difficulty in noting and verbalizing significant features, more extensive thought has been shown to enhance attitude strength. For example, attitudes formed through the careful consideration of the arguments contained in a persuasive message (central processing) are generally more accessible than those formed through peripheral processing (Petty, Haugtvedt, & Smith, 1995).

CATEGORY-EXEMPLAR ASSOCIATIONS

Structure

To this point, we have focused exclusively on the strength of object-evaluation associations. However, a second kind of association is also very relevant to consumer choice behavior — that between the representation of a category and an exemplar or instance of the category. These category-exemplar associations also vary in strength such that activation of the category can automatically activate particular exemplars and vice versa. For example, the category "U.S. Presidents" will cause many people to automatically retrieve exemplars such as George Washington and George W. Bush. These individuals have not only often been thought of frequently, but also have been frequently thought of *as Presidents*, whereas other exemplars (e.g., Rutherford B. Hayes) may be more weakly associated with the category and are not as likely to be activated automatically by the relevant category.

One property of category-exemplar associations that distinguishes them from attitude-object associations is their bidirectionality. The likelihood that an exemplar automatically activates a category may differ from the likelihood that that category automatically activates that exemplar. To use the previous example, the likelihood that the category "U.S. Presidents" will automatically activate Rutherford B. Hayes may be low for most people. However, mentioning Rutherford B. Hayes to many people will often automatically activate the category "U.S. Presidents" (and perhaps little else). This bidirectionality is less relevant to attitudes. Encountering attitude objects can automatically activate associated evaluations, but individuals don't generally encounter evaluations that activate specific attitude objects. The more useful variable tends to be the likelihood that objects automatically activate evaluations, not the other way around.

With category-exemplar associations, however, the likelihood that the category will evoke the exemplar and the likelihood that the exemplar will evoke the category are often both of interest. Additionally, it is possible for an exemplar and category to be strongly associated in both directions

such that a “unit relation” exists in which the pair has all-or-none storage and retrieval properties (Anderson, 1980). In this case, the category and exemplar will each always automatically activate the other. Consumer psychologists have recognized that it is important to consider the bi-directionality of associations between brands (exemplars) and the relevant product category (see Farquhar & Herr, 1993). The terms “category dominance” and “instance dominance” have been used to describe, respectively, the strength of the category-to-brand association and the strength of the brand-to-category association.

Category Dominance

Regarding category dominance, a brand has a relative advantage if for many individuals that brand is activated automatically from memory upon consideration of a relevant product category. This “top-of-mind awareness” has been posited as a key link between media advertising and purchase behavior (Krugman, 1965; Sutherland & Galloway, 1981). It is easy to imagine situations in which retrieving a brand from memory is a prerequisite to initiating purchase behavior, and research does indicate that brand retrieval is a predictor of choice (Nedungadi, 1990). As this would suggest, the first brand listed upon presentation of a product category is both a reliable and valid measure of repeat purchases (Axelrod, 1968). As an example, imagine that an individual has decided to order a pizza. The first brands activated in consideration of the category “pizza” have an enormous advantage. The first pizza considered, if it “sounds good” and is practical, is ordered post haste.

Indeed, consumer studies have observed that only the first brands recalled are likely to be part of a consideration set. If the first option considered is deemed desirable, actions toward acquiring that brand rather than a competitor are undertaken without further consideration, preempting the choice process (Nedungadi, 1990). This seems especially likely if the steps required to make a purchase are clear and convenient, for example if the necessary phone number is known or easily locatable and so on. Sometimes this occurs to the detriment of satisfaction with a purchase or other choice. Had the individual recalled more pizza purveyors, it is possible that another would have seemed even better, but the advantage of accessibility is such that sometimes highly accessible exemplars can be chosen even if ultimately not preferable given the full set of potential options. Category dominance, the strength of the category-to-brand association, appears to be an important determinant of consumer choice that advertisers and marketers would want to foster unconditionally.

Instance Dominance

Sometimes it may also be beneficial for advertisers and marketers to consider instance dominance, the strength of the brand-to-category association. Instance dominance is a fundamental aspect of “brand meaning” along with other brand associates like usage situations, product attributes, or customer benefits (Herr, Farquhar, & Fazio, 1996). Instance dominance for a particular brand may apply to various specific categories and also to more general categories. For example, some individuals might associate the brand Johnson’s® most strongly with baby shampoo, others with baby powder, and still others, more generally, with personal care products. These associations will influence what comes to mind upon consideration of the brand and how information about the brand will be interpreted.

Instance dominance has interesting implications for automatic attitude activation. As already mentioned, encountering an object that is an exemplar of a category may result in activation of an attitude associated with that object. Additionally, though, it has been observed that exemplars can automatically activate attitudes associated with the *category* (e.g., Fiske & Pavelchak, 1986; Castelli,

Zogmaister, Smith, & Arcuri, 2004). Presumably, this spreading activation is dependent on the strength of the exemplar-to-category association. So, consideration of a product or brand is likely to automatically activate attitudes associated with categories strongly associated with that product or brand.

This process has some interesting implications for marketers. It may be desirable for pragmatic reasons for businesses to attempt to create positive attitudes specifically towards a product category rather than a brand, even when the primary goal is in service of a particular brand. One such reason is that it may be easier to influence attitudes subtly at the category level. Social influence attempts often evoke psychological reactance (Brehm, 1966), a motivation to assert autonomy and defy another's prescription for one's behavior. The awareness that one is targeted for a persuasive message can reduce the efficacy of that message (e.g., Petty & Cacioppo, 1979). In modern society, individuals are bombarded with advertisements and consumer psychologists have recognized that consumer cynicism can be problematic (Kanter, 1989). Attempts to influence attitudes towards categories of products may be inherently more subtle because of the absence of conspicuous focus on particular brands, often an obvious cue that one is currently a target of persuasive efforts. Often when advertisements influencing attitudes at a category level are actually observed it is because businesses not representing particular brands but having a vested interest in the successful marketing of a product category are responsible, as when the National Cattlemen's Beef Association informs, "Beef—It's what's for dinner." Research demonstrating that exemplars automatically activate attitudes associated with superordinate categories provides some empirical evidence suggesting that such efforts should have the effect of influencing attitudes towards particular brands, presuming that brand-to-category associations are strong and that the fit between the object of the advertisement and the categorical mental representation of the brand is good. Upon encountering an actual product, attitudes toward the category can be as or more important than attitudes towards the brand.

Brand Extensions

It has been argued that advertisers and marketers should consider the bi-directionality of category-exemplar associations and that failure to take them into account (as when symmetry is assumed) can result in mistaken predictions about consumer choice behavior (Farquhar & Herr, 1993). The issue of brand extensions, the transfer of brand-related associations to new product categories, illustrates the necessity of considering category and instance dominance. Brand extensions are desirable because they allow new products to be accompanied by immediate brand recognition and because individuals may infer that positive aspects of brand's known product will generalize to the new extension.

Herr et al. (1996) investigated the impact of category dominance and intercategory relatedness on the transfer of associations to hypothetical brand extensions. Relatedness refers to the strength of association between the brand's parent category and the target extension category. For example, a soda company extending their brand to bottled water would have greater relatedness between the parent and target extension categories than if that soda company introduced potato chips (or swimwear). This associative strength is determined by factors including but not limited to the similarity of common features. Herr et al. (1996, Experiment 2) showed that the transfer of associations was facilitated for closely related categories relative to distantly related categories. Participants were presented with lists of 16 hypothetical extensions to real brands that varied in the relatedness of the target category to the parent category and in the strength of the category-to-brand association of

the parent category. Following a distractor task, participants' recall of the extension was measured as were liking for and intention to purchase each extension. Regarding the mental representations held by consumers, the success of a brand extension should depend, at least, on both the ease of learning the new brand-category pairing and on the transfer of affect to the extension. Participants were very successful in learning extensions when the target category was closely related to the parent category. Also, participants displayed somewhat better recall for extensions of highly category dominant brands regardless of relatedness. Affective associations also transferred more easily to extensions (according to the liking and intention to purchase measures) when intercategory relatedness was high and when the brand was highly category dominant. Furthermore, an interaction emerged such that brand extensions were viewed *most* favorably when category dominance was strong and the categories were highly related.

On the other hand, it is likely that instance dominance is a limiting factor of the extent to which brands might be stretched to other categories. A strongly instance dominant association defines a brand specifically and is likely to inhibit learning of the extension and its subsequent inclusion in consideration sets. This seems especially likely in the case of distantly related parent and target categories, in which extensions to far-flung categories may seem jarring or inappropriate given the strength with which the brand is associated with a very different class of product. Research has not fully addressed the role of instance dominance in brand extensions, and more research is required to test this reasoning. Regardless, category and instance dominance probably have different impacts on the feasibility of brand extensions, demonstrating that sometimes the nuances of associative structure are necessary considerations when predicting choice.

Determinants of Category-Exemplar Associations

The basic principles of associative strength that applied to strengthening attitudes again apply to category-exemplar associations. Various forms of repetition and rehearsal of the pairing of category and exemplar will form and strengthen connections between the two (Smith & Queller, 2001). Advertisements can be specifically designed to promote strong category-exemplar associations between product categories and brands. One form of commercial, for example, has been shown to be effective in increasing the strength of category-brand associations. *Mystery ads* leave the identity of the brand being advertised unclear until the very end of the ad, despite well-established benefits of early brand identification on message recall (Stewart & Furse, 1986). Mystery ads are intended to induce some curiosity about the subject of the ad. The technique used to achieve this can vary. A dramatic narrative might create suspense about the product's identity. Surreal or absurd commercials sometimes seem to be largely intended to provoke the question "What is this a commercial for, anyway?" Fazio, Herr, and Powell (1992) argued that mystery ads create a "readiness to categorize" the product when it is finally revealed by inducing viewers to ask "What is it?" questions. In their study, participants viewed television commercials in either their original, mystery forms, or in professionally edited non-mystery versions in which everything was identical except the identification of the brand having been moved from the end of the ad to the beginning.

Afterwards, the strength of category-brand associations was measured by the latency of response required to correctly identify the brands as belonging to their product category. The results indicated that mystery ads were more effective than traditional ads in strengthening category-brand associations. However, this effect was only observed for novel brands, ones that were promoting brands unavailable in the United States. For familiar brands, mystery ads were no more effective

than traditional ads in influencing category-brand associations. Thus, it appears that mystery ads are an effective means of introducing a new brand to a product category.

FURTHER IMPLICATIONS FOR CONSUMER PSYCHOLOGY

We have argued that object-evaluation associations and category-exemplar associations are important for understanding consumer behavior at an information processing level. The previous sections described various consequences and determinants of object-evaluation and category-exemplar associations. The applied focus has been on methods of strengthening the cognitive associations that are involved in consumer choice. Advertisers and marketers may wish to devise explicit strategies for fostering particular types of associations depending on the nature of the product and brand. To do so, however, requires some understanding of when object-evaluation associative strength versus category-exemplar associative strength is more likely to matter. When is one more likely to predict consumer behavior than the other?

Which Associations Matter?

Generally, no single type of association will be important to the exclusion of all others, but sometimes it will be more strategically valuable to focus efforts on creating or strengthening specific associations in memory. Posavac, Sanbonmatsu, and Fazio (1997) investigated the impact of whether decision alternatives are self-generated or presented externally to the decision-maker. In a series of two session experiments, participants first generated a list of worthwhile charities (along with several other lists to obscure its significance) and were later asked in a second session unexpectedly to choose a charity to receive a small donation. This choice occurred under one of two conditions. Participants were either required to write their choice on a blank piece of paper or were first provided with a list of charities by the experimenter. Studies 1 and 2 showed that when alternatives were provided to participants, the charity chosen was highly consistent with their self-reported attitudes, but when alternatives had to be self-generated, decisions were less consistent with attitudes. Instead, choice was better predicted by the order in which participants generated charities during the first session—an indicator of category-exemplar accessibility. In Study 3, participants were not presented with a list of charities when they made their decisions. During the first session, participants either did or did not repeatedly rehearse the *category membership* of several charities. Notably, when the accessibility of several charities had been increased, the decisions again were highly consistent with attitudes. Thus, when several strong category-exemplar associations were available and a larger set of exemplars readily came to mind in response to the category consideration, participants comparatively evaluated the favorability of the alternatives on the basis of their attitudes, much as they did when the alternatives had been presented by an experimenter.

Attitudes are generally more likely to guide behavior when alternatives are salient, whether in memory or the environment. After all, attitudes involving strong object-evaluations are automatically activated as a response to the object being encountered. Some cue must be present for the evaluation to be activated. When behavioral alternatives must be self-generated, category-exemplar associations necessarily play an important role. Only accessible exemplars can be included in a consideration set. The research findings highlight the role of influencing attitudes as the major goal of advertisement for the many products that are typically encountered in consumer situations involving environmentally salient alternatives. When a brand appears in a supermarket, for example, surrounded by eye-catching, competitive alternatives, category-brand associations are

rendered largely irrelevant. On the other hand, when decisions are made in the absence of salient alternatives, the most favorably evaluated option may not be chosen. The example of ordering pizza again comes to mind. Regarding an individual, perhaps sitting on a couch, wondering from where to order pizza, category-brand accessibility is paramount.

However, a point made previously bears repeating in this context. The impact of associative strength and accessibility on consumer judgment is greatest when individuals are not motivated to recall or seek out many choice alternatives and are not motivated to effortfully reevaluate the merits of the relevant product rather than relying on preexisting attitudes. Thus, the role of associative strength will generally be more important for routine, inexpensive purchases rather than purchases which elicit some fear of choosing poorly. Also, associative strength will also play a greater role in situations in which the opportunity to deliberate or seek out alternatives is low, as when decisions occur under time pressure.

Situational Cues

Associative strength and accessibility have been thus far presented as susceptible to social influence (e.g., advertising) but basically as fixed characteristics that the consumer essentially brings to the choice situation. So, individuals enter a consumer situation with some pre-existing associative structure of mental representation pertinent to the purchase decision which determines what concepts will be activated as objects are encountered in the environment. Though this is often what happens, it is also possible for environmental cues to activate associative representations in memory or elicit the formation of new associations, rendering irrelevant their chronically low accessibility or absence. Through point-of-purchase displays and other techniques, it is possible to increase the likelihood that desirable attitudes or category-exemplar associations are activated—ones that may promote the desired consumer behaviors.

An example of how cues can be used to form or activate desired associations comes from an experiment by Snyder and Kendzierski (1982). These researchers demonstrated that attitude-behavior consistency can be increased by exposing individuals to an attitudinal cue just before a choice is required. In their study, participants' attitudes toward psychological research had been previously measured and all selected participants had positive attitudes toward psychological research. Upon arriving for the experimental session, participants encountered two confederates reading a notice posted on the wall. The notice requested that participants sign-up to return for two future sessions for a small compensation. Two confederates were always present. One read the notice aloud and asked, "I don't know whether I should volunteer or if I shouldn't volunteer. What do you think?" In the control condition, the other confederate replied "Beats me—It's up to you." Or, the second confederate replied "Well, I guess whether you do or don't is really a question of how worthwhile you think experiments are." When a situational cue provoked participants to assess their attitudes toward psychological research, the percentage of participants who signed up for further participation more than doubled, reflecting greater attitude-behavior consistency given that all the selected participants believed psychological research to be meritorious. In such a manner, an appropriate situational cue can induce individuals to activate or construct associations that would have otherwise not influenced behavior, enhancing attitude-behavior consistency.

Measurement

Having hopefully made a case for the importance of the strength of association between various representations as determinants of consumer behavior, we will conclude with some comments for

those who may be interested in measuring associative strength. Fazio, Williams, and Powell (2000) investigated the validity of three methods of assessing the strength of category-brand associations. The researchers identified one particular method as providing essentially a “gold standard” measure of category-exemplar associations. The procedure involves presentation of a category label as a prime, followed by presentation of a visually degraded exemplar that gradually becomes less obscured. The degree to which the category prime facilitates recognition of the exemplar is the most direct indicant of the extent to which the exemplar is spontaneously activated when the category is considered. This measure minimizes the potential role of individuals’ immediate goals and conscious retrieval strategies. When feasible, this method is recommended, but each of the two other methods that were examined was substantially correlated with the facilitation measure. One such procedure involves latency to a direct query, which was employed in many of the experiments summarized in this chapter. The latency required for individuals to correctly categorize exemplars as members or non-members of a specific category can be used to measure the strength of category-exemplary associations. Both the priming measure and the direct query measure require the electronic measurement of latencies. A far easier method of assessment was also found to be valid, corroborating previous research (Axelrod, 1968). The order in which participants listed brands following a category cue also reflects associative strength. This simple order-of-output measure is especially well-suited to field research methodologies requiring easily-administered, paper-and-pencil assessments.

Many readers will be aware that there has been a surge in the development and use of indirect or implicit measures of attitude in recent years (see Fazio & Olson, 2003, for a review). A proper discussion of the merits of various measures and their appropriateness for particular research problems is beyond the scope of this chapter. Nevertheless, a few brief comments are in order, for the implicit measures hold the potential for providing important insights. The most frequently used implicit measures of attitude, affective priming (Fazio, Jackson, Dunton, & Williams, 1995) and the Implicit Association Test (IAT, Greenwald, McGhee, & Schwarz, 1998), are especially pertinent in this context because they involve inferring attitudes from the latencies with which participants categorize objects. The priming measure is based on the paradigm described earlier for investigating automatic attitude activation; attitudes are inferred from the extent to which a given prime facilitates identification of the connotation of positive versus negative evaluative adjectives. The IAT assesses the ease with which participants can associate the dual meanings of a given response key. Is performance better when the presentation of a given type of object is to lead to responding with the same key that signifies “good” or when the response to that object is mapped onto the key that also represents “bad?” In other words, these methods reflect associative strength rather than deliberative evaluations. Individuals may not realize that their attitudes are being assessed during these procedures (more true, in our view, of the priming procedure). Or, if they do come to such a realization, it is difficult for individuals to misrepresent one’s attitudes, provided they follow the task instructions (more true, in our view, of the IAT). Another difference between IAT measures and affective priming ones is that IAT measures seem to primarily reflect the associations between the category labels and their evaluations, whereas affective priming measures reflect the associations between the particular exemplars used and their evaluations (see Fazio & Olson, 2003). Researchers in consumer psychology should consider this distinction when choosing what kind of implicit attitude measure is most appropriate for the task at hand.

For research involving certain types of attitudes, for instance those probing for prejudicial attitudes, implicit measures of attitude are almost a necessity due to concerns about the truthfulness of responses and social desirability effects. Though individuals generally have little motivation to misrepresent their attitudes in most consumer studies, implicit measures may be nevertheless

desirable at times. For example, participants who believe (accurately or not) that the experimenter wishes them to express (dis)liking for a particular brand over another may do so regardless of their actual attitudes.

Some evidence has been offered in the domain of consumer psychology for the IAT's validity and predictive utility (Brunel, Tietje, & Greenwald, 2004; Maison, Greenwald, & Bruin, 2004). Moreover, an experiment conducted by Brunel et al. (2004, Study 2) demonstrates the potential for divergence between implicit and explicit measures of attitude within an advertising context. Participants viewed multiple ads for sneakers. Each ad consisted of a spokesperson and a brand logo. Attitudes toward the ad itself were assessed by explicit measures and the IAT. The critical manipulation was whether the spokesperson was White or Black. On explicit, semantic differential measures, white participants professed equally positive attitudes toward the ads with Black and White spokespeople. On the IAT, however, white participants showed an implicit preference for the ads with White spokespeople. Regardless of the specific interpretation of these findings and their relation to individuals' "true" attitudes, this type of divergent finding is worthy of consideration. Consumer psychologists should be aware that implicit measures of attitude can suggest different inferences than those revealed by explicit measures. In accord with Fazio and Olson (2003), we believe that as more is learned about the mechanisms that underlie implicit measures, and the appropriate inferences to be drawn from them, they will become increasingly valuable tools for understanding choice behavior.

Measuring the Nonconscious

Implicit Social Cognition in Consumer Behavior

INTRODUCTION

Current research in psychology suggests that much of human behavior is influenced by uncontrolled, unobserved processes in memory (Bargh, 2002; Greenwald et al., 2002). Despite this increased attention to nonconscious processes within academic psychology, consumer research has largely neglected this nascent field: reviews of the last fifteen years of consumer behavior research report a focus on research methodologies that directly tap conscious beliefs, but which provide little insight into underlying implicit processes (Cohen & Chakravarti, 1990; Jacoby, Johar, & Morrin, 1998; Simonson Carmon, Dhar, Drolet, & Nowlis, 2001). As an example, research into the structure and function of attitudes has relied almost exclusively on explicit measures, encouraging the development of theories dependent on conscious evaluation and deliberation. Although these theories are essential to the advancement of the field, they often neglect the potential role of nonconscious processes. Moreover, the validity of explicit measures is threatened if subjects do not possess an attitude prior to measurement, are unable to access an attitude in memory, or are unwilling to share that information (Dholakia & Morwitz, 2002; Dovidio & Fazio, 1992; Fazio, 1986; Fazio & Williams, 1986; Gur & Sackeim, 1979; Hawkins & Coney, 1981; Louie, Curren, & Harich, 2000; Orne, 1962; Taylor & Brown, 1994). In sum, explicit measures are an important component of any behavioral research program, but they often illuminate only a partial picture of consumers' underlying cognitions.

INTEREST IN IMPLICIT MEASURES OF SOCIAL COGNITION

Interest in what are now identified as “implicit” measures of social cognition has increased as the limitations of self-report measures have become more apparent. The most recent, well-established, and popular of these new measures is the Implicit Association Test, or IAT (Greenwald, Mcghee, & Schwartz, 1998). The IAT is a computer-based categorization task designed to measure relative strengths of association among concepts in memory without requiring introspection on the part of the subject. The IAT is easy to implement, generates large effects sizes, and possesses good reliability (Greenwald & Nosek, 2001). While initial applications of the IAT focused on implicit attitude measurement (Greenwald, Mcghee, & Schwartz, 1998; Greenwald & Nosek, 2001), researchers have expanded its usage to include measures of self-concept (Farnham, Greenwald, & Banaji, 1999; Greenwald et al., 2002; Greenwald & Farnham, 2000; Perkins, Forehand, & Greenwald, 2005; Perkins, Forehand, & Greenwald, 2006; Spalding & Hardin, 1999), stereotypes (Greenwald et al., 2002; Nosek, Banaji, & Greenwald, 2004; Rudman, Greenwald, & Mcghee, 2001), self-esteem (Farnham, Greenwald, & Banaji, 1999; Greenwald et al., 2002), implicit egotism (Jones, Pelham, Mirenberg, & Hetts, 2002; Pelham, Mirenberg, & Jones, 2002), and implicit partisanship (Greenwald, Pickrell, & Farnham, 2002; Perkins et al., 2006). As many of these concepts appear regularly in consumer behavior research, application of the IAT in consumer psychology seems like an obvious and viable opportunity.

AN EXPLANATION OF THE IAT METHODOLOGY

The IAT (Greenwald, McGhee, & Schwartz 1998) is an indirect measure of relative strength of association between concepts or objects in memory. The IAT procedure requires subjects to quickly map items representing four different categories onto two responses on a computer keyboard (e.g., pressing two prespecified keys such as “D” and “K”). Following the appearance of a category exemplar on the computer screen, a respondent categorizes the item as quickly as possible by pressing the response key that represents its appropriate category. The ease or difficulty with which a subject is able to assign the same response to distinct concepts is taken as a measure of strength of the association between them in memory. The following discussion is meant to familiarize the audience with the IAT method: several recent reviews (Brunel, Tietje, & Greenwald, 2004; Nosek, Greenwald, & Banaji, 2005) examine related methodological and psychometric issues.

Consider a *brand attitude* IAT designed to assess relative attitudes toward Coke and Pepsi. This attitude IAT requires the use of four categories, each having multiple exemplars. The two brand categories (Coke and Pepsi) are referred to as *target concepts*. The remaining two categories are the *attributes* that may be variably associated with the target concepts. In an attitude IAT, the attribute categories are *pleasant* and *unpleasant*. Typical target concept and attribute categories include between three and six stimulus items (category exemplars), although IATs with as few as two items per category have been effective (Nosek, Greenwald, & Banaji, 2004). Exemplar items for a target concept or attribute category can include images, brand logos, and/or words.

A typical IAT has a sequence of five *discrimination tasks*. Each task serves either to train the respondent in the appropriate responses to a given set of stimuli, or to measure the speed with which the subject can categorize concepts and attributes when they share a response key. The initial discrimination task involves distinguishing items of the two target concept categories, for example, images representing Coke versus Pepsi. Often, the number of initial training trials varies with the number of stimulus items, such that each stimulus item is viewed twice, in random order. The second discrimination task parallels the first, using the attribute category stimulus items (e.g., words for *pleasant vs. unpleasant*).

In the third discrimination task, or *initial combined task*, subjects categorize a series of items drawn from both target concept categories and both attribute categories. During this task, a target concept category and an attribute category are assigned a shared response key. For example, subjects press a specified response key with one hand (e.g., the “D” key with left hand) as quickly as possible whenever a Coke category item or a pleasant attribute appears on the screen. Whenever a Pepsi category item or an unpleasant attribute item is presented, the subject would press the alternate response key (e.g., the “K” key with right hand). Stimulus items are presented alternately from the two target concept and the two attribute categories, with the particular stimulus item being randomly chosen from the available set of exemplars.

The final two discrimination tasks reverse the appropriate response for the target concepts and thereby create a task that can be directly compared to the initial combined task. In the fourth discrimination task, the *reversed target concept discrimination*, subjects practice categorizing the Coke and Pepsi target concept items with the response keys previously used for the other. If the initial target concept discrimination assigned the Coke category to the “D” key and the Pepsi category to the “K” key, the *reversed* discrimination task would assign Pepsi to the “D” key and Coke to the “K” key. This reversal serves two purposes: it allows subjects to unlearn the category-response key associations acquired during the first and third discrimination tasks, and it sets up the fifth discrimination task, or *reversed combined task*. This final task is identical to the initial combined task, with the target concept categories reversed. The critical response latency data are captured in tasks three and five.

SCORING THE IAT

The IAT measure is computed as a function of the difference in average response speed between the *initial combined task* and the *reversed combined task*. After transformation of these aggregated response times (discussed below), the difference in performance speed between the initial and reverse combined tasks provides the basis for the IAT measure. Greenwald, McGhee, and Schwartz (1998) provided a *conventional* scoring algorithm that provides detailed procedures for data reduction, difference score calculation, and IAT effect assessment. This algorithm was chosen over alternative latency-based scoring algorithms because it produced the largest statistical effects sizes.

Although effective, the conventional algorithm was selected over other latency measure scoring methods based upon the effect sizes it produced rather than any theoretical reasoning (Greenwald & Nosek, 2001). To establish a psychometrically preferable measure, a new scoring algorithm was developed: the *D* measure (Greenwald, Nosek, & Banaji, 2003). The *D* measure differs in several ways from the conventional scoring procedure. The *D* measure is computed by dividing the difference between the congruent and incongruent test blocks by the standard deviation of the aggregate test-block latencies. This was justified because the magnitudes of differences between experimental treatment means are often correlated with the variability of the data from which the means are computed. Using the standard deviation as the divisor adjusts differences between means for this effect of underlying variability (Greenwald, Nosek, & Banaji, 2003). As a result, the *D* measure is similar to Cohen’s *d* (Cohen, 1977) and may be interpreted as an effect size. However, where Cohen’s *d* uses the pooled standard deviation *within treatment* as the divisor, the *D* measure computes an *inclusive* standard deviation from all latencies in the two combined tasks of the IAT (Greenwald, Nosek, & Banaji, 2003). Further, the *D* measure includes data from both practice and test blocks as well as the data from the first two trials in test blocks (these data are dropped in the conventional scoring procedure due to typically lengthened latencies). The inclusion of these additional trials improves the stability of the measure and increases correlations with explicit measures.

Overall, recent analysis suggests that the D measure is a superior measure to the conventional scoring procedure as it increases the magnitude of effects measured using the IAT, leads to higher correlations between the IAT and explicit measures, and increases the predictive validity of IAT scores on behavioral dependent variables (Perugini, 2004). A full discussion of the D measure may be found at <http://faculty.washington.edu/agg/>, where one can download analysis scripts that calculate the conventional and the improved D measure (as well as other measures discussed in Greenwald et al. (2003)). The current authors recommend using the D measure, not only because it has been shown to be a superior measure to the conventional scoring procedure, but also because its use will increase the interpretability and comparability of results across disciplines and experiments by providing an effect size-like statistic.

APPLICATIONS OF THE IAT IN CONSUMER BEHAVIOR

Implicit Attitude Measurement

Starting with Allport's declaration that attitude is "social psychology's most indispensable concept" (Allport, 1935), the psychological definition of *attitude* has evolved. In general, attitude has been defined as inclination toward evaluation, whether it be "a disposition to react favorably or unfavorably to a class of objects" (Sarnoff, 1960) or "an individual's disposition to respond favorably or unfavorably to an object, person, institution, or event, or to any other discriminable aspect of the individual's world" (Greenwald, 1989). To say that attitude measurement is a cornerstone of social psychology historically and consumer behavior more recently is not hyperbole. Surveys of recent developments in consumer research (Cohen & Chakravarti, 1990; Jacoby, Johar, & Morrin, 1998; Simonson et al., 2001) are replete with a staggering array of models that describe people as creatures of conscious, careful, analytical decision making. Consumers are thought to be active, rational processors of the vibrant stimuli in their environment, consciously parsing information, deciding about what to attend to, discarding irrelevant or extraneous information, and weighing what is left over in order to optimize value and facilitate attitude creation. This social cognition paradigm is epitomized by the development of two related models of persuasion: the elaboration likelihood model (ELM) (Petty, Cacioppo, & Schumann, 1983) and the heuristic-systematic model (HSM) (Chaiken, 1987). These theories provide a foundation for models of advertising effectiveness, purchase decisions, and brand and product attitude development. Interestingly, while the focus of ELM and HSM is clearly conscious and cognitive, both models propose that consumers may be influenced by inputs that are not consciously analyzed. By incorporating nondeliberative judgment into the process, these theories are the precursors to newer theories that advocate attitude development in the absence of overt cognition.

The notion that attitudes might develop as a byproduct of nonconscious, automatic, or implicit process gained momentum in the early 1990s (Bargh, Chaiken, Golder, & Pratto, 1992; Bargh, Chaiken, Raymond, & Hymes, 1996; Bargh, Chen, & Burrows, 1996; Fazio, Powell, & Williams, 1989), spawning the notion of *implicit* attitudes—"introspectively unidentified (or inaccurately identified) traces of past experience that mediate favorable or unfavorable feeling, thought, or action toward social objects" (Greenwald & Banaji, 1995). Implicit attitudes are thought to be more strongly influenced by nonconscious processing due to their independence from conscious adjustment and evaluation. Thus, it is common to observe dissociation between explicitly self-reported attitudes and implicit attitudes measured by nontraditional methodologies like the IAT. Initially, these disassociations prompted theorizing that implicit and explicitly stated attitudes may be independent constructs (Devine, 1989; Greenwald & Banaji, 1995), while more recent theorizing sug-

gests that implicit and explicit measures assess related but distinct constructs in memory (Nosek & Smyth, 2005). However, interpretations of IAT results have generally not been committed to a theoretical position on the question of whether implicit and explicit measures of attitude tap two types of indicator of a common construct (single-process theories), tap two distinct constructions (dual-process theories), or represent general cultural knowledge versus personal attitudes (Greenwald & Nosek, 2007).

USING THE IAT TO ASSESS IMPLICIT CONSUMER ATTITUDES

Within consumer research, there are many domains in which similar disassociations between explicit and implicit attitudes may occur. Constructs that have relied on self-report measures for description such as vanity (Netemeyer, Burton, & Lichtenstein, 1995), stigmatized behaviors (Mowen & Spears, 1999; Swanson, Rudman, & Greenwald, 2001), or the exploration of “dark side behaviors” such as drug and alcohol use (Mick, 1996) may be affected by subject unwillingness to accurately report due to social desirability biases. One of the first examples of the IAT being applied to problems of this sort examined behavioral and attitudinal responses to spokesperson race in print advertising (Brunel, Tietje, & Greenwald, 2004). Prior research revealed low correlations between explicit and implicit measures when the focus of attitudinal measurement is related to race, suggesting that explicit measures are consciously modified as a result of self-presentation bias or reluctance to report true feelings (Dasgupta et al., 2000; Greenwald, Mcghee, & Schwartz, 1998). Thus, the question of interest was whether the IAT would pick up negative attitudes related to the race of celebrity spokespersons. To this end, advertisements were created that paired brand information with athletes, and which manipulated the race of the celebrity sportsperson. Interestingly, White respondents exhibited a significant “pro-White” preference when measured with the IAT, but did not reveal a significant preference on self-report measures. On the other hand, Black respondents indicated a preference for advertisements with Black spokespersons on self-report measures, but no significant implicit preference. Further, the magnitude of implicit preference for advertisements that included White spokespersons was significantly greater for White respondents than for Black respondents, whereas the opposite was true for the self-report measures. Further analysis confirmed a significant interaction of ethnicity and measurement method on the revealed preference for advertisements with spokespersons of one’s own ethnicity.

A number of other researchers have used the IAT to explore the effects of implicit attitudes on judgments as well. For example, Forehand and Perkins (2005) found that favorable attitude toward a celebrity positively influenced response to advertising utilizing that celebrity’s voice, but only when the subject was unable to identify the celebrity behind the voice. This influence reversed if the subject could correctly identify the celebrity, was motivated to eliminate irrelevant influences, *and* was able to consciously adjust response (an adjustment that was only possible on explicit measures). Using set/reset theory (Martin, 1986), the authors argued that this reversal on explicit measures was due to *resetting*, a correction of the perceived influence of the celebrity cue due to its logical irrelevance. The disassociation between the explicit and implicit results suggested that resetting requires explicit evaluation. This experiment also demonstrates that the IAT can be used to discern the underlying processes that produce effects traditionally observed on explicit measures.

Maison and colleagues (Maison, Greenwald, & Bruin, 2001) conducted a number of experiments exploring domains where one might expect dissociation between explicit and implicitly measured attitudes. One of these studies explored attitudes toward high- and low-calorie products. For these products, it was hypothesized that consumers (young women) hold ambivalent attitudes, perceiving high-calorie products as good in taste, but bad for their health and perceiving low-calorie

products as bad in taste, but good for their health. When attitudes toward these food products were measured using traditional explicit measures, results suggested that young women preferred high calorie products on some dimensions (e.g., taste). However, implicit attitude measures revealed that young women had more positive attitudes toward low calorie products. Moreover, favorable implicit attitudes toward low calorie products predicted dieting activities.

Another set of experiments investigated consumer ethnocentrism. Consumer ethnocentrism is defined as a conscious preference for one's own native products (e.g., products produced within your country or region) compared to foreign products (Verlegh & Steenkamp, 1999; Watson & Wright, 2000). Consumer ethnocentrism may result from any number of different mental processes: cognitive (people believe that products produced in their own country are better), affective (people have a positive affective reaction toward native products), or ideological or normative (people believe that it is appropriate to purchase products manufactured in their own country). Until recently, consumer ethnocentrism was studied in developed countries using explicit measures and this typically revealed a bias in favor of products produced in the subject's native country. However, in less economically developed countries this domestic preference is often not observed. This is thought to be the result of experience with poorer-quality native products compared to foreign brands. Maison and colleagues predicted that this situation can lead to dissociation between implicit and explicit attitudes and could produce internal conflict between automatic preference based on emotions and rational judgment based on observation and experience.

Thus, two experiments were conducted to explore explicitly and implicitly measured preferences toward foreign versus local products and their relationship to behavior. The first study measured attitude toward Polish versus foreign brands of cigarettes, on the assumption that Polish cigarettes were considered to be lower quality than foreign brands of cigarettes. Subjects completed an attitude IAT that incorporated Polish (e.g., Sobieskie, Carmen) and American (e.g., Marlboro, Camel) cigarettes brands and filled out a survey measuring their opinions and attitudes toward these brands. Interestingly, the explicit measures revealed that the subjects preferred foreign brands, while attitude IAT suggested that the subjects preferred the Polish cigarette brands. This dissociation was stronger among nonsmokers than among smokers, while smokers smoked foreign brands and reported a preference for the foreign brands of cigarettes but still revealed a slight preference for Polish brands using the IAT. A second experiment replicated these findings across a number of product categories.

The IAT has been used to explore other types of associations in memory beyond attitude. For example, recent research into the processing and understanding of brand slogans suggests that a significant component of the understanding of brand slogans may be implicit in nature (Dimofte & Yalch, 2004). Brand slogans may have implicit influence on belief to the extent that they are *polysemous* (i.e., the extent they possess both a literal and figurative meaning). For example, Hoover's brand slogan is "Deep down you want Hoover," a statement that implies both cleaning power and consumer's inner desire for the brand. Dimofte and Yalch suggest that polysemous advertising slogans (those that include both literal and figurative meanings) may be processed differently by consumers, according to ability to access meanings. Dimofte and Yalch argued that, in the case where a polysemous slogan incorporates literal and secondary slogans that potentially differ in valence, one would expect differential responses to those slogans to the extent that the viewer of those slogans was able to discern both meanings.

To test these hypotheses, three versions of an experimental advertisement were created using two well-known automobile brands: Lexus and Mercedes-Benz. The advertisements were identical in their presentation of comfort and performance attributes, but differed in the slogans that were included in the advertisements: "Unlike any other" (literal positive), "No one comes close" (poly-

semous mixed, such that the secondary negative reading suggests that it is too expensive and thus unattainable for the vast majority of automobile buyers) and “For the few who can afford it” (literal negative). The IAT was used to measure subjects’ automobile brand associations with attributes related to “expensive” versus “affordable.” Consistent with expectations, Dimofte and Yalch found that subjects who were better able to access multiple meanings of the slogans exhibited a significant “Mercedes + Expensive” association suggesting that these subjects implicitly understood the secondary slogan meanings. On the other hand, subjects who were unable to access the multiple meanings of the slogans did not appear to process the secondary, implicit meaning of the slogan, suggesting that different cognitive processes were occurring between the groups.

A follow-up experiment by Dimofte and colleagues (Dimofte, Yalch, & Greenwald, 2003) suggested that incidental exposure to an object could produce novel implicit associations with that object. A particular brand name (Trojan) that could both represent a “party”-related product and the mascot of a major American university was chosen as a stimulus item. After incidental exposure to the brand name and logo, subsequent implicit associations of that specific university and the concept of “party” emerged robustly among subjects familiar with both categories. Further, the strength of this novel implicit association was enough to reverse perceptions of the target university when compared to another, comparable university that was explicitly considered more of a “party” school (UCLA). A similar result was obtained using a different brand name that could trigger positive or negative valence depending on the context. To the extent that the context primed either positive or negative valence, subsequent implicit measures of brand attitude revealed valence-consistent associations with the brand in question.

PREDICTING CONSUMER BEHAVIOR WITH THE IAT

Previous research suggests that the ability of the IAT to predict behavior is somewhat inconsistent, with some projects finding adequate predictive ability (Greenwald & Farnham, 2000; McConnell & Leibold, 2001; Rudman & Glick, 2001) and others not (Karpinski & Hilton, 2001). A recent meta-analysis (Poehlman et al., 2006) of IAT research in psychology (including 14 consumer behavior studies) found that both IAT and explicit measures reliably predicted behavior, and that implicit measures were superior in predicting stereotyping and prejudicial behaviors. Explicit measures were better predictors of behavior only when predictions by both implicit and explicit measures were both relatively strong.

Recent consumer behavior studies incorporating the IAT have found that the IAT does predict behavior. For example, purchase intention, brand preference, and perceived brand superiority were all predicted by implicitly measured self-brand association (Perkins, 2005). Further, these relationships were completely mediated by implicit attitude toward the brand. These results are consistent with the notion that self-concept association with objects directly influences attitude formation and behavior (Bargh & Chartrand, 1999; Greenwald & Banaji, 1995; Perkins, Forehand, & Greenwald, 2005; Perkins et al., 2006).

Interestingly, explicit and implicit measures of brand attitude predict brand choice differentially. When under time constraints, consumer brand choice was significantly influenced by prior implicit attitude, while explicitly reported attitudes were more diagnostic when consumers had more time available (Wanke, Plessner, & Friese, 2002). Similarly, Plessner and colleagues (Plessner, Wanke, Harr, & Friese, 2004) looked at the effect of time pressure on product choice of recycled versus nonrecycled writing pads, finding that implicit attitudes toward recycled versus nonrecycled paper predicted product choice only when subjects were required to make the product choice within a 5-second response window, while explicit measures predicted product choice when there

was no response window limitation. Taken together, these findings suggest that cognitive resource limitations may lead people to base choices on implicit associations in memory, since they lack the cognitive resources to go through conscious deliberation. While exploring consumer behavioral situations where a dissociation between explicit and implicit attitudes might occur, Vantomme and colleagues (Vantomme, Geuens, De Houwer, & De Pelsmacker, 2004) suggested that implicit measures of negative attitudes toward “green” or ecologically friendly products should be both dissociated from explicit measures of attitude toward green products, and be less likely to predict product choice, because it was thought that negative implicit attitudes toward green products should be consciously modified by subjects. Interestingly, the reverse was true: implicit attitudes were found to be extremely positive toward green products, and predicted green product choice.

THE SELF-CONCEPT IN CONSUMER BEHAVIOR

Recent research suggests that many cognitive processes related to the self-concept and its effect on behavior may be unconscious or beyond active control (Bargh, Mckenna, & Fitzsimons, 2002; Farnham, Greenwald, & Banaji, 1999; Greenwald et al., 2002; Greenwald & Farnham, 2000; Hetts, Sakuma, & Pelham, 1999; Spalding & Hardin, 1999). This differs from previous theorizing about the self-concept, which suggests that self-related cognitions tended to be conscious, active processes (Higgins, 1987; Higgins, Klein, & Strauman, 1985; Markus, 1983; Markus & Nurius, 1986; Markus & Nurius, 1987; Meyers-Levy & Peracchio, 1996). The idea that cognitive processes related to the self-concept may unconsciously influence behavior builds from prior research that suggests that people process social information at both an explicit and implicit level (Bargh et al., 1992; Devine, 1989; Fazio et al., 1986; Greenwald & Banaji, 1995). For example, automatic or implicit process have been observed in stereotype activation and resultant behavior (Bargh, Chen, & Burrows, 1996), automatic attitude formation (Greenwald & Banaji, 1995), self-esteem development (Farnham, Greenwald, & Banaji, 1999; Greenwald et al., 2002), implicit egotism (Jones et al., 2002; Pelham, Mirenberg, & Jones, 2002), implicit partisanship (Greenwald, Pickrell, & Farnham, 2002; Perkins et al., 2006), and self-concept organization (Perkins, Forehand, & Greenwald, 2006).

The influence of the implicit self-concept has been explored in a number of domains. For example, people exhibit automatic minimal group bias, but were unaware of the bias at an explicit level (Ashburn-Nardo, Voils, & Monteith, 2001). Greenwald and Farnham (2000) found low correlations between implicitly and explicitly measured self-esteem and self-concept, suggesting differences in the constructs tapped by each measurement technique. Further, implicitly measured self-esteem predicted expected mental buffering following manipulations of success versus failure. Spalding and Hardin (1999) found that implicit self-esteem predicted anxiety during an interview. Swanson, Rudman, and Greenwald (2001) reported inconsistent attitude-behavior relationships for smokers using both implicit and explicit measures. Overall, there seems to be evidence that the self-concept operates at an implicit level, and that the implicit self-concept may reveal different associations and attitudes compared to the explicit self-concept.

One of the newest areas of exploration that leverages much of the methodological development of the IAT is a project by Perkins, Forehand, and Greenwald (under review). The authors introduce the notion of *implicit self referencing*, or the automatic self-association of objects encountered in the environment and subsequent generation of a positive implicit attitude toward those objects. Recent research (Greenwald et al., 2002), in the tradition of cognitive consistency theory (Festinger, 1957; Heider, 1958; Osgood & Tannenbaum, 1955), suggests that self-object relationships are tied to implicit identities (self-group associations). Greenwald et al. (2002) theorized interrelations among triads composed of the following components: the *self*, a *group*, and an attribute such as *valence*.

Thus, a linkage between the self-concept and valence is interpreted as *implicit self-esteem*, (Farnham, Greenwald, & Banaji, 1999; Greenwald & Farnham, 2000), an association between an object and valence is interpreted as an *implicit attitude* (Greenwald et al., 2002) and an association between a group or object and the self-concept is interpreted as an implicit *identity* (Rudman, Greenwald, & McGhee, 2001). Although the research cited here focuses primarily on self-group interactions and notions of identity, a long tradition in social psychology and consumer behavior has argued that objects (in the form of gifts, products, or brands) may help define identity as well (Aaker, 1999; Belk, 1988; James, 1890; Kleine, Kleine, & Kernan, 1993; Tietje & Brunel, 2005; Wicklund & Gollwitzer, 1982). Tietje and Brunel (2005) applied these theories to establish a unified brand theory framework and experimental results that examine the existence and influence of these existing triads in memory. The authors' previous research (Brunel, Tietje, & Greenwald, 2004) provides initial support for the unified theory framework, finding that Macintosh users revealed stronger self-Macintosh association than PC users revealed self-PC association. They suggested that Macintosh users identify with Macintosh due to the minority status of Macintosh in the marketplace, the strong sense of community that surrounds Macintosh users, and the notion that, while PC users are generally compelled to use PCs due to work availability, Macintosh users must actively choose the brand, usually incurring social and professional difficulties. Tietje and Brunel (2005) propose a theoretical framework that incorporates self-esteem, attitudes, stereotypes, and self-concept similar to Greenwald and colleagues (2002) framework.

Perkins and colleagues have extended these theoretical and experimental findings to the creation of new attitudes toward novel stimuli items, such as brands. Greenwald and Banaji (1995) define *implicit self-esteem* as "the introspectively unidentified (or inaccurately identified) effect of the self-attitude on evaluation of self-associated and self dissociated objects" (p. 11). Numerous studies (Taylor & Brown, 1994) have established that the majority of people report favorable self-descriptions and self-evaluations, suggesting that a link in memory exists between the self-concept and a cognitive representation of positive valence. To the extent that a new link is created between the self and some object in the environment, perhaps due to environmental exposure, one would expect a new link to form between that object and a positive valence representation (i.e., forming or increasing a positive attitude). This should occur not require either conscious input or awareness of attitude formation by the subject.

Two experiments bear this out. In the first experiment, subjects were randomly assigned to perform a categorization task that created a trivial link between their own self-concepts and an innocuous object, in this case either *analog* or *digital clocks*. These target concept categories were extensively pretested to ensure that pre-experimental implicit attitudes toward the two categories were, on average, approximately equal. The categorization task required subjects to categorize target concepts (images of either *analog* or *digital clocks*) and attribute items (words representing the concepts of "self" and "other") in specific pairs. For example, subjects who were randomly assigned to associate self with *analog clocks* did a categorization task that required the same response (pressing the computer's "D" key) when items that represent *self* or *analog clocks* appeared on the screen, and required a different response (pressing the "K" key) when items that represent the concept *other* (opposite of self) or images of *analog* clocks appeared on the screen. No specific explanation of this purpose of the categorization task was provided. Phase 1 required subjects to complete two blocks of 36 trials each categorizing *digital* and *analog* clock images with the attributes *self* and *other*. The response key ("D" or "K") was reversed for both contrasts in the second categorization task to avoid associating any concept with a specific key response.

After this associative practice, subjects completed an IAT that measured implicit attitudes toward the target concepts. It was hypothesized that the association practice would create a new

link in memory between the self and one of the target concept categories, indirectly producing an association of positive valence with that concept. This was precisely what was found: subjects who (for example) associated self with analog clocks subsequently showed IAT-measured positive implicit attitudes toward analog clocks.

Experiment 2 replicated Experiment 1, but added a twist: instead of a self-association task designed to create a link between the self-concept and a known but previously unlinked object category in memory (clocks), Experiment 2 incorporated invented brand names that were unknown to the subjects. Again, the brand names were pretested to make sure that the subjects did not prefer one of the brand name sets (ACE and STAR, each with four invented model names) prior to the manipulation. In order to facilitate the learning of the new brand names, subjects were presented with a static list of the brand names for 30 seconds prior to the self-categorization task. Following the self-categorization task, subjects again completed attitude IAT. The same results as Experiment 1 obtained: Subjects who self-associated with the ACE brand, for example, automatically generated a positive implicit attitude toward the ACE brand relative to the STAR brand. Taken together, these results suggest that attitudes may be automatically generated toward objects as a result of merely self-associating that object. The research question is now whether we can pin down automatic self-association.

An extension of this implicit self-referencing project examined the possibility that implicit attitudes may be spontaneously formed as a result of a self-group association. Previous research suggests that simply learning the names of randomly assigned team members leads a subject to associate self with that team (Greenwald, Pickrell, & Farnham, 2002). This automatic self-group association has been shown in related research as well. Pinter and Greenwald (2004) found that automatic self-group association led to differential resource allocation amongst competing teams. Perkins and colleagues (Perkins et al., 2006) sought to further understand mere group membership by looking at its effects on brand attitude formation in two experiments.

Under the guise of a scavenger hunt, subjects were instructed that they would be randomly assigned to one of two fictitious groups, named “circle” or “triangle.” In order to learn their group membership, subjects were first exposed to a list of names either of members of the subject’s or another, competing group. Following this exposure, subjects practiced categorizing the names of their own and the competing team to become familiar with the names and the group memberships. The subject’s group included four names, and the word “myself” representing the subject’s membership in that category, while the opponent group included five names.

Subjects were next instructed to learn a set of objects pretested to assure that they were, on average, initially equivalent in evaluation: *analog* or *digital clocks* (Study 1) or fictitious automobile brand names Ace or Star (Study 2; the experimental design differed only with regard to the stimuli employed between the two studies). These objects were to be the target of a fictitious scavenger hunt on the campus where the experiments were run. However, the categorization task required here was different from the task employed in the implicit self-referencing project described above. Subjects categorized their team members’ names and one of the target objects using the same response key. For example, if the subject was on the circle team, and was assigned to find the Ace automobile brand names, then the categorization task required giving the same response when either circle team names or Ace brand names were presented, and a different response when triangle team names or Star brand names were presented. For this categorization task, only four names from each team were used, allowing omission of “yourself” stimuli. Thus, during the second categorization task, the subject never categorized any explicitly self-identified stimuli with the target objects. Following these tasks, subjects completed a self-target object IAT (either clocks or brands) and a parallel attitude IAT for the target objects.

The results revealed that subjects spontaneously generated positive implicit self-associations as well as positive implicit attitudes toward the target objects that were sorted together with the names of their group's members during the experimental treatments. Specifically, subjects in the circle group, who categorized their group members with the Ace brand model names, subsequently self-associated with and generated a positive implicit attitude toward the Ace brand, even though there was no direct linkage of self with the Ace brand during the experiment. These results extend the implicit self-referencing experiments described above: instead of examining the spontaneous creation of an implicit attitude that is the direct result of implicit self-association, these two experiments revealed a positive implicit attitude resulting from merely being associated with a group that was in turn associated with the arbitrarily assigned target object.

Finally, Forehand and colleagues (Forehand, Perkins, & Reed II, 2003) explored self-identity and responses to advertising stimuli in three experiments. Prior research demonstrates that accessible and self-important social identities affect judgments in predictable ways, and has identified three main classes of variables that may influence identity accessibility—enduring traits such as strength of identification with a specific identity, aspects of the social context in which a consumer resides, and contextual primes that can activate or prompt identity-based processing (Forehand et al., 2003). In these two experiments, consumer sensitivity to situational manipulations of distinctiveness (McGuire, McGuire, Child, & Fujioka, 1978) was assessed using standard explicit self-report measures and IATs. The IATs measured the degree to which each subject associated specific self components (gender and ethnicity) with identity-related concepts and thereby provided implicit measures of identity accessibility. During a preliminary phase of the first two experiments, subjects completed a battery of demographic items, personality scale items, and implicit identity IATs to provide baseline measures of their prevailing identity accessibility. Several weeks after this initial measurement, the subjects participated in an ostensibly unrelated experiment in which the composition of the subject's immediate social environment was either measured (Experiment 1) or manipulated (Experiment 2). It was hypothesized that identity accessibility during this second session would be influenced not only by the subject's distinctiveness within their immediate social context, but also by general sensitivity to such social information (as measured using Snyder's self-monitoring scale). Forehand and colleagues found that social distinctiveness did influence both explicit and implicit identity accessibility, and that the influence of distinctiveness on identity accessibility was moderated by the subject's predisposition toward self-monitoring, such that high self-monitors were influenced by social cues to a greater extent than were low-self monitors. This pattern of results was observed on both explicit and implicit measures of identity accessibility.

Forehand et al.'s (2003) third experiment assessed the degree to which the expression of an identity-based preference reinforces identity accessibility. It was hypothesized that the use of one's identity as an informational cue in attitude expression reinforces the accessibility of that identity and thereby increases the likelihood that the identity will be used in subsequent judgments. To test this hypothesis, college-age subjects evaluated advertisements for vitamins intended for children, young adults, or seniors and then completed an Implicit Association Test designed to measure self-association with youth versus aged. Compared to subjects who evaluated the young adult version of the ad (the control condition), subjects who evaluated the children-focused ad or the senior-focused ad demonstrated stronger self-youth associations. This finding suggests that the use of an identity dimension in an evaluation activates preexisting identity associations. Since the majority of consumers possess preexisting strong associations between the self and youth (Nosek, Banaji, & Greenwald, 2002), this identity activation increased the self-youth association.

CONCLUDING REMARKS

Since its introduction, the IAT has exploded in popularity and usage. While previous reviews (Brunel, Tietje, & Greenwald, 2004; Nosek, Greenwald, & Banaji, 2005) have explored various psychometric and methodological issues, the purpose of this chapter is to review the most recent examples of IAT usage in consumer behavior research. It is hoped that this review will serve as a launching pad for marketing researchers to become familiar with current research streams and to start exploring the unconscious or implicit processes that most of us believe underlie much consumer behavior. The current state of theoretical development, methodology, and areas of application form a “perfect storm” of exciting, valuable, and rewarding research, and the opportunity to incorporate what seems to be a major component of social cognition—the nonconscious role of implicit cognitive processes in consumer decision making and behavior.

NOTES

1. Steps 4 and 5 are reversed here as a result in a change in the scoring algorithm following publication of Greenwald et al. (2003). The published algorithm requires the calculation of standard deviation prior to error trial replacement. The description here (error trial replacement followed by standard deviation calculation) is corrected.

Implicit Consumer Cognition

PATRICK T. VARGAS

University of Illinois at Urbana-Champaign

The ubiquity of advertising in daily life was bad enough for consumers in September of 1957. But the thought that advertisers were scheming to deprive consumers of their free will by advertising to the subconscious was just too much to bear. James M. Vicary and Francis Thayer had announced that they presented messages such as “Eat popcorn” and “Drink Coca-Cola” for a duration of 1/3000th of a second, well below the threshold for conscious perception, during movie screenings. According to Vicary and Thayer, this subliminal persuasion technique increased popcorn sales 57.5% and cola sales 18.1%. Some unseen stimulus allegedly influenced consumers to buy more snacks at the movies. The implications were staggering: politicians could use subliminal advertising to get elected; anyone who had enough money to subliminally advertise on television could make an unsuspecting public do their bidding. Even a suspecting public might be susceptible to subliminal advertising, since there would be no way know whether advertisements were being played.

Outraged letters and editorials appeared in major magazines and newspapers; both the U.S. Congress and the Federal Communications Commission debated the legal and ethical implications of subliminal advertising. In June, 1958, American networks and the National Association of Broadcasters banned subliminal advertising. The best available evidence, however, suggested that subliminal advertising simply did not work. Vicary’s attempts to duplicate his claims under controlled conditions were unsuccessful, at best. In a June, 1962, interview in *Advertising Age*, Vicary admitted that his claim was fraudulent.

No advertising- or consumer-related claim has captured the public imagination quite like the notion that consumers can be persuaded *outside of their conscious awareness* to buy. Vance Packard’s (1957) best seller, *The Hidden Persuaders*, described nefarious tricks used by marketing and advertising professionals designed to appeal to consumers’ unconscious needs and desires. Published only two years later, Haber’s (1959) survey of 324 San Fransiscans revealed that 41% were aware of subliminal advertising, and 50% believed it to be unethical. Still, two-thirds of them were willing to watch a television program even if they knew that subliminal advertising was used in the commercials.

Surveys conducted more recently (Rogers & Smith, 1993; Synodinos, 1988; Zanut, Pincus, & Lamp, 1983) reveal that the public has substantially greater familiarity with subliminal advertising today. Between 74 and 82% of respondents (depending on the survey) claimed to have heard of subliminal advertising. Of those respondents who have heard of subliminal advertising, more than 99% believe that subliminal advertising is actually used and 44 to 48% of respondents believe that they may be susceptible to subliminal advertising. The threat of subliminal advertising has not abated; instead, in the past 50 years the general public has become more aware and more suspicious

of subliminal advertising. As described in greater depth later in this chapter, public concern over the power of subliminal advertising is likely quite unfounded. Subliminal advertising is, at best, a very weak force.

However, there *is* evidence that subliminally presented stimuli can influence affect, behavior, and cognition. And subliminal stimulation is not the only way in which we can be influenced without awareness. Consumer-related affect, behavior, and cognition can be, and often is, driven by forces that are at entirely outside of conscious awareness.

IMPLICIT (CONSUMER) COGNITION

The concept of subliminal advertising is but one example of a broader class of phenomena that may be grouped under the label implicit consumer cognition. Before addressing the more specific implicit consumer cognition, consider first implicit cognition, more generally. Implicit cognition is evidenced by the influence of past experience on some task, without conscious recollection or awareness of the influencing experience (e.g., Greenwald & Banaji, 1995; Khilstrom, 1990, 1999; Roediger, 1990; Schacter, 1987).

A classic example of implicit cognition may be found in the study of memory. When presented with a list of words to memorize, amnesiacs show very poor performance on recall and recognition tasks compared to nonamnesiac control subjects. Amnesiacs do not seem to have introspective access to memory. However, when presented with an identical list of words and later asked to complete a series of word fragments or word stems (e.g., c_k_ or pep_ _), the amnesiacs produce previously seen words at essentially the same rate as nonamnesiacs. That is, amnesiacs' past experiences have an influence on subsequent performance that is nearly identical to nonamnesiacs; their implicit memory is every bit as good as unimpaired control subjects (Warrington & Weiskrantz, 1970).

In recent years research on implicit cognition has moved well beyond memory, to the study of social cognition (e.g., attitudes, stereotyping, self-esteem; Greenwald & Banaji, 1995) and, by natural extension, to the study of consumer cognition. Implicit consumer cognition is the unacknowledged or misidentified influence of past experience on consumer-related judgment and behavior. Consumer cognition may be implicit in different ways: Consumers may be unaware of some biasing stimulus (as in the subliminal advertising example); they may be unaware of cognitive processes mediating the relationship between some stimulus and an outcome, or they may be unaware of the actual outcome (Chartrand, 2005). To what extent, though, is consumer behavior driven by influences and processes of which we are unaware?

Decades of research have shown a reliable impact of explicit cognition on consumer behavior. Different models of human cognition have portrayed people as naïve scientists (engaging in careful, semiscientific attempts to understand the world around them), cognitive misers (of limited cognitive capacity, and generally unwilling to expend full cognitive effort), and motivated tacticians (possessing multiple processing strategies and using them according to motivation and ability) (Fiske & Taylor, 1991). Despite numerous differences, all of these models clearly posit the utility of explicit cognition. People process information intentionally and effortfully, and doing so often leads them to correct decisions. In studies of attitude change, for example, people who are both motivated and able to carefully process persuasive information generally come to accept high-quality arguments, and reject low-quality arguments (e.g., Petty & Cacioppo, 1986). Of course, persuasion need not involve extensive cognitive elaboration. People can also be persuaded by lightly processing peripheral cues (e.g., an attractive model may engender positive feelings toward a brand) or by evoking heuristics (e.g., a highly credible source would only endorse a good product).

But given our limited cognitive resources, and the volume of stimuli we encounter each day, it is surely impossible to devote even small amounts of our cognitive resources to *all* of the stimuli we encounter each day. Clearly we cannot always engage in thoughtful, systematic information processing (Bargh, 1997; Kahneman & Triesman, 1984; Posner & Snyder, 1975; Schneider & Shiffrin, 1977). Sometimes our performance is improved when we devote less attention, or fewer cognitive resources, to decisions (e.g., Ambady, Hallahan, & Conner, 1999; Ambady & Rosenthal, 1992, 1993; Dijksterhuis, 2004). Indeed, our frequent inability to correctly explain our own behavior (Nisbett & Wilson, 1977) speaks directly to the notion that we lack conscious awareness of many basic cognitive processes. If we were consciously aware of how and why we do things, we ought to be able to coherently explain how and why we do them. In fact, we are so bad at explaining our own behavior that attempting to do so often fouls up the behavior we are trying to explain (Wilson & Kraft, 1993; Wilson & Schooler, 1991; Schooler, 2002; Schooler, Ohlsson, & Brooks, 1993).

In a remarkably compelling (if somewhat inhumane) example of our inability to make accurate attributions about our behavior, a nonstuttering research participant was induced to stutter via negative reinforcement (Goldiamond, 1965). He was given electric shock while reading aloud, and the shock was stopped only when the participant stuttered. At the end of the session, his rate of stuttering was so high that he received no shocks at all. Two days later he came back to the lab and stuttered so frequently that he was shocked only twice. When asked about his stuttering, he attributed it to his anxiety. When asked directly whether the electric shock could have impacted his stuttering, he claimed that shock had nothing at all to do with his stuttering. Sometimes cognition occurs outside of conscious awareness (in this example, an awareness of the stuttering-shock contingency), and this cognition can have important implications for our behavior, including consumer behavior.

A contemporary explosion of research on implicit cognition continues to reveal ways in which mental processes that occur outside of conscious awareness can have a profound impact on judgment and behavior. This chapter is a review of research and theory on implicit cognition as it applies to consumer behavior, organized into two main sections. The first section addresses implicit measures of attitudes (other than the Implicit Association Test, see chapter 17, this volume), affect, memory, and personality. The second section is devoted to implicit processes and effects, including subliminal persuasion and priming, consumer decision-making, and verbal overshadowing.

IMPLICIT MEASURES

Explicit measures are those that require the respondent to intentionally retrieve some stored information about him- or herself. Explicit attitude measures, such as Likert, Thurstone, or semantic differential measures, require respondents to retrieve stored evaluative information about a particular attitude object. Explicit measures of personality require respondents to indicate the extent to which different trait words, or behaviors, accurately describe them. According to accepted wisdom explicit measures are best used when respondents are willing and able to report on their psychological states. Explicit measures ought to work fine when used to assess attitudes or personality traits of which respondents are consciously aware, and are not wrought with social desirability concerns. On the other hand, explicit measures are thought to be of quite limited utility when the object under consideration is socially undesirable (e.g., prejudice [Crosby, Bromley, & Saxe, 1980], attitudes toward cheating [Corey, 1937]). When people are either unwilling or unable to report their true attitudes, conventional wisdom would advocate the use of implicit, or indirect measures.

Implicit measures also assess stored information about the respondents, but they do not require the respondent to intentionally retrieve the information. Instead, information about the respondent

is inferred from the responses to tasks or questions that ostensibly have nothing to do with the respondents' psychological state (attitude, trait, etc.). A classic example of implicit measures is the Thematic Apperception Test (TAT; Morgan & Murray, 1935). The TAT is a projective measure, in which respondents are shown a series of ambiguous images, and asked to write a brief story about each image. Trained coders then rate the story according to prespecified criteria, giving the respondent a score on the dimension of interest (e.g., Need for Affiliation [Winter et al., 1998], attitudes toward union labor [Proshansky, 1948]). Projective implicit measures have fallen out of favor due to perceptions about poor validity and reliability (Lemon, 1973; but see Lundy, 1985; Winter & Stewart, 1977). Contemporary implicit measures rely more on the speed with which respondents can perform certain tasks, such as word categorization; or make word-non-word judgments (e.g., Dovidio, Kawakami, Johnson, Johnson, & Howard, 1997; Fazio, Jackson, Dunton, & Williams, 1995; Greenwald, McGhee, & Schwartz, 1998). The Implicit Association Test (see Perkins, chapter 17, this volume) and the evaluative priming paradigm (Fazio et al., 1995; Wittenbrink, *in press*) are two such measures. Although both response-time based measures and projective-type measures can be implicit, they seem fundamentally different in terms of the type of information processing each requires.

Different Classes of Measures

In 1964 Cook and Selltiz published an article describing a basic taxonomy of attitude measures. What is remarkable about their taxonomy is the fact that, over 40 years since its publication, it continues to hold up well enough to account for all extant attitude measures. Further, although their analysis was intended to address attitude measures, only, the five classes of measures they identified are more broadly applicable to measures of other constructs such as personality, affect, self-esteem, and so forth.

The first class of measures identified by Cook and Selltiz was self-report measures, now known as explicit measures, in which respondents simply report their attitudes by responding to direct questions. Self-report measures are of obvious importance and utility, but they are not the primary concern here. The second class was behavioral measures, in which attitudes were inferred based on the observation of behavior (e.g., Byrne, Ervin, & Lamberth, 1970; Milgram, Mann, & Harter, 1965; Webb, Campbell, Schwartz, Sechrest, & Grove, 1981). Today behavior is considered more of an attitudinal outcome than an attitude measure (but see Albarracín & Wyer, 2000, Ouellette & Wood, 1998). A third class was comprised of physiological measures. At the time, physiological measures included galvanic skin response, pupillary response, and the like; contemporary physiological measures are far more sophisticated and require expensive and sophisticated equipment (e.g., Cacioppo, Crites, Berntson, & Coles, 1993; Ito & Cacioppo, 2007). The fourth and fifth classes described by Cook and Selltiz are of greatest interest for the present chapter because they are implicit measures, and they have important implications for measurement, predictive ability, and even our understanding of the broader constructs that we are attempting to measure—attitudes, personality, and so forth.

The fourth class of measures identified by Cook and Selltiz (1964) was labeled partially structured (PS) measures. Use of these measures involves presenting respondents with ambiguous stimuli: "while there may be no attempt to disguise the reference to the attitudinal object, the subject is not asked to state his own reactions directly; he is ostensibly describing a scene, a character, or the behavior of a third person" (p. 47). Thus, projective tests fall into this category. Attitude researchers have used projective tests to differentiate between known groups (Proshansky, 1943), and consumer researchers have used such measures to assess attitudes toward different products.

Haire (1950) presented consumers with 7-item shopping lists that were identical except for the type of coffee: half of the respondents read a list that contained Maxwell House drip, and half read a list that contained Nescafe instant. Participants were asked to make judgments about the woman who made the list. They were more likely to describe the woman who used Nescafe as “lazy,” “a poor planner,” and a “bad wife,” suggesting quite negative attitudes toward instant coffee. These classic measures are no longer frequently used, but attitude researchers continue to develop new PS measures.

The Affective Misattribution Paradigm (AMP; Payne, Cheng, Govorun, & Stewart, 2005) fits the profile of PS measures perfectly. The AMP is a computer-mediated task that simply requires participants to evaluate previously unseen, ambiguous Chinese ideographs. The ambiguous ideograph rating task is preceded by the brief (supraliminal) presentation of “real life” images (i.e., attitude objects under consideration, such as African American or Caucasian faces, or images of two competing brands). Participants’ ratings of the ideographs are assimilated to their spontaneous, unintentional evaluative responses to the real life images. For example, a Dallas Cowboys fan’s ratings of ideographs preceded by Dallas Cowboys imagery would be more positive than those preceded by Pittsburgh Steelers imagery, whereas the opposite would be true for the Steelers fan. Remarkably, participants are given instructions explicitly warning them against being influenced by the real life images, yet evaluative responses to the attitude objects reliably influence ratings of the ideographs. AMP scores reliably correlate with explicit attitude measures, and with self-reported behavioral intentions (i.e., voting intentions; Payne et al., 2005, Study 5). Other types of PS measures have been used to predict behavior in domains with, and without, social desirability concerns.

Vargas, von Hippel, and Petty (2004) developed a measure based on respondents’ tendency to contrast information away from their own attitudes (see also Edwards & Smith, 1996; Lord, Ross, & Lepper, 1979). Participants were presented with a series of vignettes describing different characters engaged in ambiguously conflicting behavior. For example, one of the vignettes designed to assess attitudes toward religion was about a character who described herself as “very religious” but who had not attended church services in several years. Instead, she occasionally watched religious programming on television. Following each vignette respondents were asked to indicate how religious they thought each character was (using a pair of 11-point semantic-differential type scales). As expected, religious respondents tended to describe the character as not very religious, and atheistic respondents tended to describe the character as quite religious. Participants’ judgments of the targets’ religiosity were treated as an implicit (PS) measure of their religious attitudes. This PS measure reliably predicted unique variance in participants’ self-reported religious behavior, beyond that predicted by traditional, explicit measures. Similar effects obtained with different vignettes assessing attitudes toward dishonesty, and toward political liberalism and conservatism (Vargas et al., 2004). This measure may be adapted to assess brand attitudes by creating vignettes featuring characters behaving in both positive and negative ways toward a particular brand (e.g., he traveled far to buy a pair of Timberland boots, but he has never worn them outside of his house). It may also be adapted to assess attitudes toward shopping, materialism, or advertising in general. The unique predictive ability of PS measures is important, and we shall return to address this issue shortly. However, it is also important to note that PS measures are not limited to attitudinal studies.

PS measures have also been used to assess prejudice, and predict prejudiced behavior (von Hippel et al., 1995; 1997; Sekaquaptewa et al., 2003; Sekaquaptewa & Espinoza, 2004; Vargas, Sekaquaptewa, & von Hippel, 2004). One such PS measure, called the stereotypic explanatory bias (SEB), relies on Hastie’s (1984) finding that people tend to spontaneously explain mildly surprising events (see also Stangor & McMillan, 1992). The SEB measure presents respondents with mildly stereotype-congruent (e.g., Mary asked for help getting home) and -incongruent (e.g., Jenny confronted the man)

sentence beginnings, and simply asks respondents to complete the sentences in any way they see fit, so long as they are grammatically correct. High-prejudice respondents are more likely than low-prejudice respondents to explain the stereotype-incongruent sentence beginnings. The SEB measure reliably predicted the tendency to ask sexist questions to a female (Vargas et al., 2004), and stereotypic questions to an African American female (Sekaquapatewa et al., 2002). The SEB seems to emerge more when members of low-status, compared to high-status, groups behave in stereotype-incongruent ways (Sekaquapatewa & Espinoza, 2004). Finally, the SEB measure reliably correlated with a conceptually related, but different PS measure of prejudice (von Hippel et al., 1997).

One might imagine applying the SEB to consumer related research as an implicit measure of country-of-origin (COO) attitudes (see, for example, Liu & Johnson, 2005). Consider a very rough example: Respondents may be presented with sentence beginnings such as, "Paul's Hyundai broke down..." or "The odometer on Cindy's Kia rolled past 100,000 miles..." and researchers would code for continuations or explanations. Individuals with negative attitudes toward Korean automobiles would be more likely to continue the first sentence, e.g., "...for the fifth time that month," and more likely to explain the second sentence, e.g., "...because she religiously followed the maintenance schedule." Individuals with positive attitudes toward Korean automobiles would be more likely to continue the first sentence, and explain the second.

Another PS measure relies on the linguistic intergroup bias (LIB; Maass et al., 1995; Maass et al., 1996), the tendency for people to describe stereotype-congruent events more abstractly than stereotype-incongruent events. In this measure respondents are presented with ersatz newspaper articles written to be either stereotype-congruent (e.g., an article about an African American high school basketball star) or -incongruent (e.g., an article about a Jewish inner-city drug dealer), and asked to indicate the extent to which each of four descriptions, ranging from very concrete to very abstract, accurately convey the main point of each article. Greater prejudice is indicated by the tendency to endorse abstract descriptions ("Washington is athletic") of stereotype-congruent, and concrete descriptions ("Rosenberg sold drugs") of stereotype-incongruent articles. The LIB measure predicted the tendency to evaluate an African American asking for change as threatening (von Hippel et al., 1997).

An LIB measure could also be easily adapted to assess COO effects, and brand attitudes. Respondents might be asked to read favorable or unfavorable stories about specific brands (e.g., a story about a man who has driven his Volvo over one million miles; a story about a man who bought a Saab that broke down as he was leaving the dealer's lot) and asked to indicate the extent to which concrete and abstract descriptions accurately describe the main point of the story. Swedish car aficionados would likely prefer abstract descriptions of the positive stories (e.g., Volvos are reliable), but concrete descriptions of the negative stories (e.g., the Saab broke down quickly); people who dislike Swedish cars would prefer concrete descriptions of the positive stories (the Volvo has been driven far), but abstract descriptions of the negative stories (Saabs are unreliable).

Personality theorists have also made use of PS measures. In administering the TAT measure, respondents are presented with a series of different images, instructions to be creative, and a set of four questions to guide them in writing stories about each of the images (Murray, 1965). As with other implicit measures, there is no mention of the true topic under consideration. Respondents' stories are then coded for the extent to which various motives (e.g., affiliation, achievement, power) are present. For example, David McClelland and colleagues (McClelland, 1985; McClelland, Koestner, & Weinberger, 1989) have used projective measures of individuals' need for achievement to predict long-term behavioral trends and outcomes. Such measures of need for achievement have reliably predicted entrepreneurial activity in the United States (McClelland, 1965) and in India (McClelland, 1987). Similarly, a PS measure of the inhibited power motive predicted managerial

success over 16 years (McClelland & Boyatzis, 1982), and elevated blood pressure over 20 years (McClelland, 1979).

Finally, consider measures described earlier assessing implicit memory in amnesiacs. These measures would also be included in Cook and Selltiz's PS category: the extent to which individuals can identify (previously viewed) words presented in a degraded form, or complete words when presented with fragments (e.g., Vi_____ for Viagra; Warrington & Weiskrantz, 1970). Similar word production-type measures have been used to assess affect: ambiguous word fragments may be presented that can be completed with positively- or negatively-valenced words. In a word association task, respondents may be presented with words and asked to generate associates; affective valence of the words, or proportion of emotion-related words, may then be coded. Participants may be given unfamiliar words and asked to rate the valence of those words (Tesser, Millar, & Moore, 1988). In another technique, participants may be told that they had been subliminally presented with a word and asked to select the word they believe was presented from a list. The list from which participants are asked to choose contains an emotion-laden word and some similar-sounding, but affectively neutral foils (Twenge, Catanese, & Baumeister, 2003). Participants tend to select words congruent with their current affective states. Certainly such measures may be used to tap implicit responses to advertising.

Cook and Selltiz's (1964) fifth class of measures was identified as measures of performance on objective tasks (OT). When using these types of measures respondents are presented with, "specific tasks to be performed; they are presented as tests of information or ability, or simply as jobs that need to be done" (p. 50). Classic attitudinal measures of this type include Hammond's (1948) error choice method, in which respondents were presented with an "information test." Items in the test were of two types: the first provided response options that were equidistant and in opposite directions to the truth. For example, "A hypothetical Wal-Mart store employing 200 people would cost local taxpayers [a] \$220,750 or [b] \$620,750 per year because of Wal-Mart's low wages and poor benefits packages." The respondent's answer was believed to be influenced by her attitude, such that individuals with positive attitudes toward Wal-Mart would select option a, and those with negative attitudes option b. The second type of question also presented two response options, but the true answer to the question was indeterminate. For example, "Wal-Mart's relationship with the general public could be characterized as [a] *benevolent* or [b] *malevolent*." Again, responses to this question should be influenced by attitudes toward the object under consideration. Other classic OT measures include respondents' ability to judge the validity of logically flawed but emotionally charged arguments. In one such study, students from Northern colleges were more likely to accept as true logically flawed arguments in favor of integration, and against segregation; students from Southern colleges tended to show the opposite pattern (Thistlethwaite, 1950; see also Selltiz & Cook, 1966; Waly & Cook, 1965).

Contemporary versions of the "objective tasks" category include the IAT (Greenwald et al., 1998) evaluative priming procedures (Fazio et al., 1995), the affective Simon paradigm (De Houwer & Eelen, 1998), the Go/No-Go Association Task (Nosek & Banaji, 2001), and the emotional Stroop task (Williams, Matthews, & MacLeod, 1996). None of these contemporary measures requires the obfuscation of the attitude object under consideration, and all are presented as tasks to be performed. Respondents are asked simply to categorize words, make word-nonword judgments, or identify words. Further, contemporary OT measures are quite flexible, and have been used to measure attitudes toward a wide variety of objects, including prejudice, self-esteem, and so forth. The IAT has emerged as the preeminent OT implicit measure, and is covered in depth in this volume (Perkins et al.). Here it may be useful simply to note the existence some other OT implicit measures. As with PS measures, though, OT measures are not limited to attitudes.

The use of implicit measures began with an OT measure of memory. Ebbinghaus (1885/1964) developed a method for studying the effect of consciously inaccessible prior experience on current thought and/or behavior. This first implicit memory measure, called savings, involved a simple procedure. Respondents learned some material, were induced to forget the material via interference, time, etc., and were then asked to relearn the (apparently novel) material. The savings, or difference in speed with which respondents were able to learn the material the second time, serves as a marker of implicit memory. (Of course, the savings paradigm may be used to measure memory whether the material is consciously accessible or not, but it would seem to be particularly useful when material is not consciously accessible.)

An OT measure of affect was developed by Mayer and Hanson (1995). This measure was presented as an “association and reasoning scale” and required participants to respond to different types of questions. One type of question asked participants to indicate “How many thoughts, images, and associations are brought to mind by the word:” and presented positive and negative words (e.g., peace, disappoint). Another type of question asked respondents to indicate the probability of different positive and negative events occurring (e.g., getting a divorce within five years of marriage, the economy will improve within five years). The final type of question was determinant choice, asking participants to select “typical” objects from categories (e.g., types of workers). The response options were positive and negative (e.g., conscientious, lazy, honest). This affect measure correlated .3 to .5 with self-report mood measures.

The description of different types of measures above is not intended to be an exhaustive compendium of all possible implicit measures. Such a task is well beyond the scope of this chapter, especially since new implicit measures seem to be introduced at a very rapid pace. The critical point is that contemporary and classic implicit measures still fit into a distinction between PS and OT that was first suggested over 40 years ago. But it may not be wise to remain content with a categorization scheme simply because it has longevity. Just as there are numerous ways to parse knowledge and information processing (e.g., semantic vs. episodic, procedural vs. declarative, heuristic vs. systematic, etc.) there may be different ways to parse implicit measures.

A Different Classification Scheme

From an information processing perspective Cook and Selltiz’s (1964) PS and OT measures have more common ground than differences with one another. It is certainly true that some implicit measures involve the presentation of highly ambiguous stimuli, and others have more of an “objective” feel. However, both types of measures rely on the tendency for some characteristic of the individual (e.g., attitudes, personality, mood) to influence the way in which relevant stimuli are responded to. As noted by Cook and Selltiz, PS measures rely on the notion that “perception of stimuli that are not clearly structured is influenced by the perceiver’s own needs and dispositions... the expressed response corresponds directly to the individual’s attitude” (pp. 47–48). Similarly, OT measures rely on the notion that, “performance may be influenced by attitude, and that a systematic bias in performance reflects the influence of the attitude” (p. 50). These analyses of the mechanisms underlying PS and OT measures may easily be applied to implicit measures in other domains, as well. Thus, the distinction between PS and OT measures is based more on the differences in the types of stimuli presented to respondents than on the differences in the process underlying responses to the measures. From an information processing perspective, PS and OT measures are quite similar to one another, and yet not all implicit measures are created equal.

We know that some implicit measures differ from others in terms of what aspects of the individual they are tapping. In an excellent demonstration of these differences Smith and Branscombe (1988)

had participants either study 24 trait words, or generate those words from behavioral instances and the first letter of the target word (e.g., attended church three times a week = r_____). Next, participants were given one of three memory measures. Two of the memory measures were implicit (category accessibility or word-fragment completion), and the third was explicit (free-recall). Performance on the memory measures was dependent on the type of studying done. Among participants who received the free-recall explicit test, those who generated the words did better than those who read them. Participants who received the word-fragment completion implicit measure showed the opposite pattern: those who read the words did better than those who generated them. But participants who received the category accessibility implicit measure performed more like those who had received the explicit measure: those who generated the words did better than those who read the words. Why would two implicit measures obtain such different patterns of results?

Implicit memory measures may be dissociated from one another because they tap different aspects of learning. The word-fragment completion measure was more sensitive to visual features of the written words, and the reading study condition allowed respondents to focus on similar aspects at study. Respondents who read the words were able to focus on how the words appeared on the printed page, and the word-fragment completion measure similarly taps perceptual information processing. The category accessibility measure was more sensitive to conceptual features of the words, and the generation study condition allowed respondents to focus on the meaning of the words. Test performance was dependent on the degree of match between type of information processing at study and testing phases. Lee (2002) presented very similar results from a set of studies where respondents read brand names in sentences or in isolation, and were given either a word-fragment completion task (perceptual processing) or a “list brands belonging to a particular product category” task (conceptual processing). Participants who read brands in sentences showed better performance on the implicit measure tapping conceptual processing, and those who read brands in isolation showed better performance on the implicit measure tapping perceptual processing. The type of information processing required by an implicit measure might thus be a valuable way to differentiate implicit measures (see also DeCoster, Banner, Smith, & Semin, 2006; Bassili & Brown, 2005).

Each implicit measure likely taps aspects of the individual that are untapped by other implicit measures. So there may be as many ways to differentiate implicit measures as there are measures. However, we may easily differentiate many contemporary implicit measures that rely on response time, and the speed with which respondents can perform tasks, from those that require more careful, deliberative information processing, such as the TAT. Implicit measures may be differentiated by the type, or level, of cognitive processing required to complete the measure. Implicit measures that rely on response times may be categorized as spontaneous; implicit measures that rely on more extensive cognitive processing may be categorized as deliberative; however, this distinction should not be considered a dichotomous split.

No implicit measure may be said to be “process-pure.” That is, implicit (and explicit) measures likely involve some aspects of both spontaneous and deliberative information processing (Bassili & Brown, 2005). Even a measure such as the IAT requires respondents to consciously focus on the task at hand, intentionally select one from the different categories to which a target word may belong, and dutifully press a button corresponding to that category. That said, it is clear that some measures rely more on spontaneous information processing, and others rely more on deliberative information processing. The labels spontaneous and deliberative may best be considered anchors at opposite ends of a continuum of information processing. Response time-based measures tend to fall toward the spontaneous end of the continuum, and other implicit measures may be scattered along the remainder of the continuum.

Why Type of Processing Should Matter

There are several interrelated reasons to expect that type of information processing should be a meaningful way to parse implicit attitude measures. First, the type of information processing tapped by a measure might be directly related to the type of behavior one can predict with the measure (Blaxton, 1989; Morris, Bransford, & Franks, 1977; Roediger, 1990). Behaviors, like implicit measures, lie along a continuum ranging from spontaneous to deliberative. Following Fazio's (1990; Fazio & Towles-Schwen, 1999) MODE model of attitude-behavior relations, we might expect that some behaviors are driven by spontaneously activated attitudes, and other behaviors are driven by more carefully thought-out attitudes (see also Ajzen & Fishbein, 1977; Vargas, 2004). To the extent that a measure taps spontaneous processing, it might be expected to predict more spontaneous behavior.

Response time-based implicit attitude measures have reliably predicted some spontaneous behaviors such as nonverbal friendliness toward African American confederates (Dovidio et al., 1997), and condom use with casual partners (Marsh et al., 2001), but they have also been shown to predict somewhat more deliberative behaviors such as smoking, vegetarianism (Swanson, Rudman, & Greenwald, 2001), and consumer choices (Maison, Greenwald, & Bruin, 2004; Wänke, Plessner, & Friese, 2002). Response time-based attitude measures seem to occasionally predict both spontaneous and more deliberative behaviors. However, a case might be made that smoking, vegetarianism, and consumer brand choices may be habitual, automatic behaviors that require little deliberative processing. Vegetarians likely do not think carefully about choosing steak or broccoli; smokers often light up without any awareness of having done so (indeed, many smokers can recall a time they have found themselves facing one lit cigarette in hand, and another in a nearby ashtray); heavy users of Diet Coke do not seem to deliberate over whether to buy Diet Pepsi or Diet Coke. Nevertheless, the data do not match the theory perfectly. The likely cause of this discrepancy between theory and data is the fact that neither implicit measures nor behaviors are process-pure; however, it remains plausible that measures tapping more spontaneous (deliberative) information processing are more likely to be related to behaviors that are more spontaneous (deliberative).

Explicit and implicit measures of personality have also been hypothesized to predict different types of behavior. McClelland, Koestner, and Weinberger (1989) have suggested that implicit measures tap a "more primitive motivational system derived from affective experiences" (p. 690), whereas explicit measures tap "a relatively well-developed concept off the self... and some ideas acquired during socialization as to what is valuable" (p. 697). They have provided evidence for the notion that implicit measures of personality are more closely related to long-term behavioral tendencies where pleasure is derived from the behavior, itself. Explicit measures of personality, on the other hand, are more closely related to immediate behavioral choices where pleasure is derived more from social reinforcement of the behavior.

The second reason to expect that type of information processing should matter has to do with the different aspects of the attitude (trait, mood, etc.) that are tapped by the different measures. Spontaneous implicit measures rely heavily on the automatic accessibility of psychological constructs. For example, both the IAT and the evaluative priming paradigm rely on the automatic activation of attitudes from memory. Thus, one would expect such measures to be particularly likely to predict behaviors that also rely on the automatic activation of attitudes. These behaviors need not be spontaneous behaviors, but they are likely to be behaviors driven primarily by automatically accessed attitudes. More deliberative measures may tap different aspects of the constructs under consideration, and predict different types of behaviors.

PS attitude measures, for example, present respondents with ambiguous stimuli and rely on the tendency for attitudes to influence the perception of that information. Many of the more deliberative OT measures operate on a similar principle. The idea is akin to the classic Hastorf and Cantril (1954) "They saw a game" study. In this study students from Dartmouth and Princeton were shown a film of a football game between the two schools. The students tended to see more fouls and examples of unfair play committed by the rival school than by their own. Their favorable attitudes toward their own schools biased the way they perceived the game (see also Lord, Ross, & Lepper, 1979; Vallone, Ross, & Lepper, 1985).

Consider another example in which one encounters an apparently unattended backpack sitting near a gate at the airport. The bag could be perceived as a place-marker for someone saving a seat in a crowded area, a lost item that ought to be turned in to lost and found, a "finders keepers" opportunity that ought to be picked up and relieved of valuables, or the container of a dangerous explosive that must be reported to the authorities. One's perception of the backpack is likely to predict behavioral response: whether one ignores, turns in, takes, or reports it. While one's evaluative feelings and beliefs (i.e., attitude) about backpacks might play some role in driving these different perceptions and behavioral responses, they are unlikely to account for the lion's share of behavioral variance. Indeed, the different behaviors are unlikely to be predicted by either an explicit attitude measure, or a measure that taps attitude accessibility. A measure that taps perceptions of ambiguous stimuli is most likely to predict behavior in an ambiguous context. Thus, measures that tap different aspects of the construct under consideration are likely to be predictive of corresponding behaviors. This analysis is not intended to imply that one should seek different attitude measures corresponding to different types of behaviors. As noted above, it is unlikely that one would find direct correspondence between the type of processes tapped by a particular attitude measure, and those processes recruited in completing some behavior. Instead, the use of multiple measures would seem most effective (Campbell & Fiske, 1959). Indeed, to the extent that each measure taps a different aspect of the critical construct that measure is likely to add unique predictive ability to a behavior or set of behaviors.

Clearly, behaviors are influenced by multiple factors (Albarracín et al., 2001; Ajzen & Fishbein, 1972; Wicker, 1969, 1971). And since different implicit measures likely tap different aspects of attitudes, it makes sense to use multiple measures in the prediction of behavior. As suggested by the need for affiliation and attitudes toward union labor examples presented above, implicit measures may have utility beyond the assessment of socially undesirable information.

Sometimes different measures will add unique predictive power, such as in Vargas et al. (2004). In a series of four studies, respondents were administered explicit and implicit measures assessing their attitudes toward dishonesty (Study 1), political liberalism and conservatism (Study 2), and religion (Studies 3 and 4). The PS measure used in these studies was described above. In simultaneous multiple regression analyses, the PS measure reliably accounted for significant amounts of unique variance, beyond that predicted by explicit measures, in both self reported behavior (all studies) and actual behavior (Studies 1 and 2). The addition of implicit measures may thus be used to add predictive ability beyond what can be obtained with explicit measures, even when social desirability concerns are not paramount.

Other studies have shown that implicit measures may interact with explicit measures to predict behavior. Constantian (1981; cited in McClelland, 1985) obtained explicit measures of the extent to which individuals preferred affiliation versus solitude, as well as an implicit TAT measure of the need for affiliation. There were two critical dependent measures: ratings of how much respondents would like taking a country walk with friends, and the proportion of respondents who were found to be writing letters when beeped (participants wore beepers, were beeped seven times a day,

and asked to write down their activities when they were beeped). Only individuals who were high on both implicit and explicit affiliation measures were significantly more favorable toward going on a walk with friends. People who had high explicit and implicit needs for affiliation liked an overtly affiliative act. However, individuals who were high on implicit need for affiliation, but low on explicit need for affiliation were most likely to be writing letters when beeped. People who had high implicit but low explicit need for affiliation were most likely to be engaged in an affiliative act that could be performed in solitude.

A pair of longitudinal studies by Winter et al. (1998) also involved the collection of implicit TAT measures of affiliation when the women were of college age, and an explicit measure of extraversion when the women were in their forties. Critical dependent measures in these studies included volunteer work, the tendency to be involved in both work and family roles, marriage and divorce, and dissatisfaction in intimate relationships. There is remarkable consistency in the results: women who showed implicit-explicit consistency (i.e., were high on implicit need for affiliation and high on extraversion, or low on both measures) fared better than their counterparts who showed implicit-explicit inconsistency (i.e., were high on implicit need for affiliation but introverted, or low on implicit need for affiliation but extraverted). Clearly, different implicit measures have utility beyond the assessment of constructs that are socially undesirable.

Implicit measures should not be considered to be secondary to explicit measures, to be used only when explicit measures are expected to be distorted due to social desirability concerns. Implicit measures can and should be used to tap different aspects of attitudes, personality, affect, and so forth, that can contribute to the prediction of behavior. By re-evaluating the utility of implicit measures we may also re-evaluate the constructs we are measuring. Consider attitudes by way of example.

Since Allport's (1935) crowning of attitude as the "most distinctive and indispensable concept in contemporary social psychology" (p. 798), the construct has gone through a number of conceptual or definitional changes. Early definitions of the attitude construct were quite broad: Allport, himself, referred to attitude as, "a mental and neural state of readiness, organized through experience, exerting a directive or dynamic influence upon the individual's response to all objects and situations with which it is related" (1935, p. 810). Krech and Crutchfield (1948) defined attitude as, "an enduring organization of motivational, emotional, perceptual, and cognitive processes with respect to some aspect of the individual's world" (p. 152). Smith, Bruner, and White (1956) defined attitude as, "a predisposition to experience a class of objects in certain ways, with characteristic affect; to be motivated by this class of objects in characteristic ways; and to act with respect to these objects in characteristic fashion" (p. 33). These older definitions of attitude contrast sharply with more limited, contemporary definitions of attitude, such as Eagly and Chaiken's (1993) widely cited definition, "a psychological tendency that is expressed by evaluating a particular entity with some degree of favor or disfavor" (p. 1). The more recent definition likely reflects the tendency in recent decades to measure attitudes with unipolar or bipolar evaluative scales (e.g., Likert, Thurstone, and semantic differential-type measures).

As implicit measures have become more common, more useful, and better understood, it seems worth re-evaluating classic definitions of the attitude construct. The relationship between measurement and theory has been well documented, as both influence one another (Ostrom, 1988). As noted above, personality researchers have come some way in integrating trait theory (typically assessed via explicit measures) and motive theory (typically assessed via implicit measures). It is time for other areas to follow suit, integrating implicit and explicit measures of different constructs. The implicit measures described herein tap much more than evaluative tendencies, and in so doing allow us to think of attitudes as less a static collection of stored evaluative thoughts, and more an

expansive, dynamic construct with many different dimensions, influencing affect, cognition, and behavior.

IMPLICIT PROCESSES: DOING WITHOUT UNDERSTANDING

In this section the focus is on the applications of implicit cognition to consumer psychology. The structure of this section is loosely based on Chartrand's (2005) model of automatic processes. According to the model, actors can lack awareness of (a) environmental stimuli that could influence their behavior, (b) automatic processes that mediate behavior, or (c) the outcome, including "behavior, motivation, judgments, decisions, and emotions" (p. 203). We begin with a review of research on environmental influences of which people are unaware (e.g., subliminal influences). Next is a discussion of automatic processes, followed by a few notes on awareness of outcomes. As in the above section, the intent is not to catalog all studies involving implicit processes and/or effects, but rather to provide an overview of the theoretical and empirical work being done in the various research areas.

Subliminal Presentation of Stimuli, and More Overt Priming Effects

Although there is little scientific doubt about the existence of unconscious mental activity, there remain serious questions about subliminal perception and the types of effects it can have. There are a variety of different problems with research involving the presentation of subliminal stimuli, but it is perhaps best to begin with definitional problems, and different usages of the term. Stimuli (visual, auditory, tactile) are said to be subliminal when they are presented in a way that evokes no sensation in a respondent. Pratkanis and Greenwald (1988) defined four categories of subliminal: subthreshold stimuli, or stimuli presented at energy levels too low to be detectable; masked stimuli, or stimuli presented very rapidly and immediately followed by another meaningless stimulus intended to interfere with perception; unattended stimuli, where attention is drawn away from the critical stimulus; and figurally transformed stimuli, including items that are blurred, decomposed, or otherwise rendered unrecognizable, even when attended to. The first two categories fit a psychological definition of subliminal because they evoke the limen.

The threshold, or limen, is the point at which a stimulus evokes a sensation. The concept of an absolute threshold, unfortunately, is essentially like the concept of the Easter Bunny. Thresholds vary both inter- and intrapersonally (Stevens, 1951), and tend to be normally distributed along a continuum. Operationally the threshold may be set by presenting respondents with a large number of trials and finding the central tendency. Items falling below this line are consciously perceived less than 50% of the time, and may be called subliminal. Note that this does not fit the limen "all-or-none" concept of threshold, making true subliminal perception a rather difficult concept to pin down. Synodinos (1988) has recommended a signal detection theory approach to identifying subliminal perception, when $d' = 0$. These approaches to operationalizing the subliminal presentation of stimuli are objective, and may be contrasted with more subjective approaches.

The emergent consensus on the most appropriate way to identify subliminal perception is to simply ask participants whether they noticed the presentation of a stimulus (Cheesman & Merikle, 1986; Fowler, 1986; Greenwald, 1992; Kihlstrom, 1987; Merikle, 1988). Analogous to the distinction between implicit and explicit memory, Kihlstrom (1999) suggested a distinction between explicit and implicit perception. Explicit perception refers to the conscious awareness of some element in the environment, and the ability to report on that element. Implicit perception is perception without awareness, and may include perceptions of stimuli that are subliminal, or supraliminal. The

critical aspect of implicit perception is the inability to consciously report on the presence of the stimuli. If respondents claim to be unable to see the stimulus, then it may be called subliminal. As Kihlstrom notes, this conceptualization also has the advantage of obviating another problem with defining subliminal perception, viz., the limen. Of course, with this approach one still has to worry about respondents being truthful, but incentives may be used to increase respondents' motivation to be truthful. Next is a brief review of research on subliminal persuasion—attempts to influence consumer behavior via the subliminal presentation of stimuli.

In general, the evidence for subliminal persuasion is quite weak. Even early studies with questionable threshold operationalizations failed to obtain reliable effects following presentation of "subliminal" stimuli. In one such study (Champion & Turner, 1959), participants were exposed to either a slide that pictured a spoon full of rice and the words "Wonder Rice" or (as a control) four lines on a black background. The exposure time, aperture opening, and slide construction were manipulated so that the experimenters could no longer detect the presence of a slide, and this was designated subliminal. Evidently, the participants were unable to detect the stimuli, either; the authors concluded that, "subliminal presentation had no effect on the responses of Ss in recognizing the stimulus figure or of associating the brand name with the stimulus figure" (p. 383). Other researchers conducted an on-air study with subliminal advertisements (as above, subliminal was operationalized by the experimenters' inability to detect the stimulus), and before-and-after measures of sales and found no effect at all (DeFleur & Petranoff, 1959). One study that did find an effect (Hawkins, 1970), was replicated only to find no effect (Beatty & Hawkins, 1989). Other studies made more careful efforts to insure that the stimuli were subliminal (George & Jennings, 1975) and still found no effect of presenting the words "Hershey's Chocolate" to experimental participants. A study of a more direct command ("choose this") similarly found no effect on respondents' intention to purchase, use, etc. (Smith & Rogers, 1994).

Many of the critiques of subliminal persuasion studies rest on methodological issues of properly setting stimuli to be subliminal¹. Moore (1982, 1988) reviewed a number of different studies, pointing out methodological shortcomings ranging from flawed operationalizations of subliminal (e.g., Cupterfain & Clarke, 1985), to logical inconsistencies in what may be expected of subliminal perception even under the best of circumstances (e.g., Kaser, 1986). Evidence for effects of subliminal auditory messages has been similarly weak to nonexistent (Greenwald, Spangenberg, Pratkanis, & Eskenazi, 1991; Merikle, 1988; Pratkanis, Eskenazi, & Grenwald, 1994; Vokey & Read, 1985), until very recently. Kouider & Dupoux (2005) found evidence for unconscious lexical repetition priming, but no evidence of unconscious semantic priming; thus, these effects are not of obvious use to consumer psychology.

In a remarkably comprehensive effort, Pratkanis and Aronson (1992) reviewed over 150 mass media articles and over 200 academic papers and found no clear evidence in support of subliminal persuasion. Pratkanis (1992) listed failures of subliminal persuasion research, "the failure to control for subject expectancy and experimenter bias effects, selective reporting of positive over negative findings, lack of appropriate control treatments, internally inconsistent results, unreliable dependent measures, presentation of stimuli in a manner that is not truly subliminal, and multiple experimental confounds specific to each study" (p. 263).

Other reviews of subliminal persuasion have been more charitable, but still pessimistic about the ultimate value of subliminal advertising. Theus (1994) concludes that there is little evidence for effects of subliminal advertising on brand choice behavior, but suggests that other applications may be more fruitful. She suggests additional research on the use of visual imagery as stimuli, recipient characteristics (e.g., using messages relevant to the audience's needs, hopes, and desires), and repetition of subliminal stimuli. Trappey (1996) conducted a meta-analysis of 23 studies on consumer

choice and subliminal advertising and found an average effect size of $r = 0.0585$. This effect, while certainly small, is not unremarkable—it is larger than the effect of aspirin on heart attacks. However, Trappey did not eliminate studies based on methodological concerns or weaknesses, and he included studies that identified embedded objects as subliminal. So this datum supporting a small effect of subliminal advertising on consumer choice must be considered generous, at best.

Despite the lack of evidence in favor of subliminal persuasion, there is a good deal of evidence demonstrating that the subliminal presentation of stimuli can have some impact on affect, cognition, and behavior. Word-nonword judgments can be speeded following subliminal presentation of a semantically related prime (e.g., priming bread facilitates recognition of butter; Balota, 1983; Fowler, Wolford, Slade, & Tassinari, 1981; Marcel, 1983). Similarly, judgments of word valence can be facilitated by the subliminal presentation of evaluatively congruent primes (Greenwald, Klinger, & Liu, 1989). Social judgments, too, can be impacted by the subliminal priming of trait words. Bargh and Pietromonaco (1982) had participants engage in a “vigilance task” in which words were presented subliminally. Either zero, 20%, or 80% of the words were related to the concept of hostility. Following the vigilance task, participants read an ambiguous paragraph about a fictional character named Donald, and rated him on a variety of dimensions. The greater percentage of hostile words they had been exposed to, the more negatively they rated Donald (see also Chen & Bargh, 1997; Erdley & D’Agostino, 1988). Finally, we know that subliminally presented stimuli can also impact attitudes.

The mere exposure effect (Zajonc, 1968) posits greater liking of a stimulus as a result of greater exposure to the stimulus. Kunst-Wilson and Zajonc (1980) subliminally presented polygons to participants via tachistoscope, and found that the more times a stimulus had been presented the better it was liked (see also Bornstein, 1992). A similar effect has also been demonstrated with the subliminal presentation of human faces (Bornstein, Leone, & Galley, 1987). Although not strictly subliminal in the subthreshold or masked sense of the term (Pratkanis & Greenwald, 1988), a similar effect was obtained with aurally presented information in a dichotic listening task (Anand & Sternthal, 1991). Further, some research has demonstrated that subliminal exposure to stimuli can also increase disliking of those stimuli (Mandler, Nakamura, & Van Zandt, 1987; Seamon, McKenna, & Binder, 1998). Subliminal primes can also be used in a value-transfer procedure. Murphy and Zajonc (1993) found that unfamiliar Chinese ideographs preceded by subliminal presentation of smiling faces were liked more than those subliminally preceded by scowling faces. And Krosnick, Betz, Jussim, and Lynn (1992) demonstrated a subliminal version of classical conditioning—preceding some faces with subliminal presentation of positive images, and others with negative images caused liking and disliking, respectively (see also De Houwer, Hendrickx, & Baeyens, 1997). The applications to advertising and consumer psychology are obvious, but inducing liking is a long way from making people get out of their seats at the movies to buy more popcorn and soda.

Other lines of research have demonstrated reliable effects of subliminal priming on judgments about the self and on behavior. For example, subliminal presentation of threatening stimuli has been shown to increase self-reported anxiety (Robles, Smith, Carver, & Wellens, 1987). A number of studies have subliminally activated stereotypes and demonstrated behavioral assimilation to those stereotypes. Elderly participants subliminally exposed to words reflecting positive aspects of the elderly stereotype (e.g., wise) have been shown to walk faster (Hausdorff, Levy, & Wei, 1999) and show improved memory (Levy, 1996); but elderly participants exposed to negative aspects of the elderly stereotype (e.g., senile) show worsened memory (Levy, 1996). Caucasian male undergraduates subliminally presented with African American faces became more hostile in the face of frustration (Bargh, Chen, & Burrows, 1996). Wyer (chapter 2, this volume) reviews additional research along these lines.

Two recent studies have shown effects of subliminally priming motives or goals on behavior, and on responses to advertising. Cooper and Cooper (2002) had participants watch an episode of *The Simpsons* and subliminally presented experimental participants with words and images pertaining to thirst, while control participants were subliminally presented with blank slides. Participants in the experimental condition subsequently rated themselves as thirstier than those in the control condition. Strahan, Spencer, and Zanna (2002) likewise subliminally primed people with either thirst-related or neutral words (Study 1) and found no effect on self-reported thirst; however, thirst-primed respondents drank significantly more liquid than neutral-primed participants. In a follow-up study, thirst-primed participants were more favorable than neutral-primed participants toward an advertisement for a thirst-quenching sports drink, but no difference emerged for an advertisement for an electrolyte-restoring sports drink. Conceptually similar results emerged in a third study, where subliminally presented sad-face primes caused respondents who expected to interact with another to prefer a mood-restoring music CD, and to choose to listen to more songs from the mood-restoring CD.

Subliminally presented stimuli can also have an impact on persuasion, but in a rather indirect fashion. Weisbuch, Mackie, and Garcia-Marques (2003) examined the effects of prior source exposure on persuasion. In two studies participants were either not exposed, subliminally exposed, or explicitly exposed to a face, and then presented with persuasive arguments ostensibly made by the same person. In both studies subliminal exposure to the source increased agreement with the arguments. The authors suggested that this effect was due to positive affect toward the source being misattributed to the persuasive arguments.

Before concluding this section it is worth briefly noting some studies that examined the effects of “subliminal” embeds on consumer response (Although, as noted above, embedded figures may more accurately be described as unattended stimuli [Pratkanis & Greenwald, 1988]). Research on sexually embedded stimuli is mixed: Two studies (Caccavale, Wanty, & Edell, 1989; Gable, Wilkins, Harris, & Feinberg, 1987) report no effect on consumer attitudes, but Aylesworth, Goodstein, and Kalra (1999) report an effect of increased upbeat feelings reported by men (but not women), and an effect of increased negativity by both men and women. Bagley and Dunlap (1980, cited in Aylesworth et al., 1999) report that sexual embeds led respondents to report feeling “turned on.” Kilbourne, Painton, and Ridley (1985) report an effect of sexual embeds on favorable attitudes toward a liquor ad, but not a cigarette ad. In a second (within subjects) study respondents showed increased GSR when shown embedded versions of the ads. The data addressing the efficacy of sexual embeds is equivocal, at best, contrary to sensationalistic claims by Packard (1957) and Key (1973, 1976, 1980).

Subliminal persuasion is, simply put, unlikely; and the effects of subliminal advertising are certainly nowhere near those suggested by Vicary. But subliminally presented stimuli can influence semantic, evaluative, and social judgments, as well as attitudes, behavior, and the processing of ostensibly unrelated information. In short, the evidence collected to date suggests that subliminal stimuli can be used to evoke abstract concepts and affect, and can influence related judgments and behaviors where the primed concepts can reasonably be availed (e.g., increase hostility in an already frustrating situation, walk more slowly when asked to walk down a hall, drink more of a beverage when thirsty). But subliminal stimuli cannot be used to directly persuade or dictate behavior (i.e., cause hostile outbursts without provocation, get up and walk down the hallway, go to the soda machine and buy a beverage). Increasing accessibility via subliminal priming is possible, and it can affect behavior to the extent that the newly accessible primes are applicable to the current situation.

An important note about the research described in this section: many of the effects described herein resulting from subliminal presentation of stimuli can also be achieved with supraliminal primes. Interested readers should consult Wyer (chapter 2, this volume) for a thorough review of accessibility effects on judgment and behavior.

At this point we consider situations in which consumers lack introspective access to their own cognitive processes. Individuals may be aware of potentially influential stimuli, and some outcome, but not of the mediating cognitive processes. The process by which supraliminal primes affect judgment, behavior, attitudes, and so forth, is outside of conscious awareness (Chartrand, 2005). Indeed, when respondents become aware of the prime's relationship with the critical dependent variable supraliminal primes tend to be ineffective (see Bornstein, 1992), or cause contrast effects, instead of assimilative tendencies. In these cases participants show reactance, or more conscious and deliberative correction strategies (see Wegener & Petty, 1995). Somewhat strangely, supraliminal primes can also cause contrast effects when participants are unaware of the prime's relationship with the dependent variable (see Wheeler & Petty, 2001). The extent to which primes can evoke contrast effects is one of many unanswered questions awaiting future research.

Aware of the Stimulus, but Unaware of the Cognitive Processes

One area where surprisingly little research has been conducted is that of actual purchasing behavior. Certainly a great deal of buying is done purposefully, intentionally, and deliberately; however, there may be innumerable forces acting outside of conscious awareness that influence what, when, and how we buy (Simonson, 2005). Morwitz, Fitzsimons, and colleagues have done a great deal of work on the mere-measurement effect (Fitzsimons & Morwitz, 1996; Fitzsimons & Shiv, 2001; Fitzsimons & Williams, 2000; Morwitz & Fitzsimons, 2004; Morwitz, Johnson, & Schmittlein, 1993; Williams, Fitzsimons, & Block, 2004). In a series of studies, these researchers have shown that simply asking consumers about their purchase intentions can increase the likelihood of purchase. Asking general, category-level questions (e.g., how likely are you to purchase an automobile?) increases the likelihood of purchase in that product category. Asking category-level questions to regular users of a brand causes greater likelihood of specific brand repurchase, and asking category-level questions to nonusers causes greater likelihood of category leader purchase.

The mere-measurement effect seems to emerge because asking intention questions increases the accessibility of attitudes toward specific members of the product category. Further, the effect seems to dissipate when respondents recognize the intention questions as persuasion attempts. Clearly, participants in these studies are aware of the environmental stimulus (i.e., a direct question about purchase intentions), but they are unaware of the automatic processes evoked by the question (increased attitude accessibility). This general idea is a familiar one: people often lack awareness of, and introspective access to, the cognitive processes mediating their behavior (Bargh, 1997; Hefferline, Keenan, & Harford, 1958; Kahneman, 2003; Langer, 1978; Lowenstein, 2001; Nisbett & Wilson, 1977).

Although Theus's (1994) suggestions for further research have been largely addressed, there are numerous unanswered questions, particularly those pertaining to the specific mechanisms by which (subliminal) priming has its effects, and the extent to which priming techniques can usefully (and ethically) be applied to consumer decisions making and behavior. Greenwald, Draine, and Abrams (1996) suggested that semantic and evaluative priming may be due to spreading activation processes; Klinger, Burton, and Pitts (2000) argued for a response competition account of the same effects. Wheeler and Petty (2001) suggested that behavioral effects of priming stereotypes may be

due to either hot (stereotype-threat) or cold (ideomotor) cognitive processes. Janiszkeski and van Osselaer (2005) proposed a nonconscious behavioral choice model wherein multiple behavioral outcomes are aroused by a prime, and the emergent behavior is selected on the basis of activation and evaluation of multiple possible behaviors. Dijksterhuis, Smith, van Baaren, and Wigboldus (2005) described low and high roads to priming effects on behavior. The low road is a simple ideomotor (mimicry) process, hard-wired in mirror-neurons found in both humans and monkeys (see Iacoboni, Woods, Brass, Bekkering, Mazziotta, & Rizzolatti, 1999); the high road is more like a spreading activation process, in which abstract concepts are activated (e.g., stereotypes, traits, goals) and concept-relevant behavior emerges, given the appropriate opportunity. Mirror neurons may be involved in concept (high road) priming, as well. Recent research suggests that mirror neurons are sensitive to contextual cues, and behavioral intentions (Iacoboni, Molnar-Szakacs, Gallese, Buccino, Mazziotta, & Rizzolatti, 2005).

In the consumer domain, it seems possible that different processes could mediate the effects of priming on subsequent tasks. Priming motives or goals may initiate hot cognition, and priming less personally involving concepts may initiate cold, ideomotor cognition. Developing a methodology to test hypotheses about mediating cognitive processes will represent a major step toward improving our understanding of priming. Since most of the work on implicit cognition—including subliminal perception—has been conducted by cognitive psychologists, we are only now beginning to scratch the surface of social and consumer-related applications.

A different line of work wherein people appear to have very limited introspective access to their own cognitive processes is in the use of “thin-slices” of behavior to make judgments. Ambady and colleagues have demonstrated that people can make surprisingly accurate and reliable assessments of easily observable personality traits, interpersonal motives, and job performance based on very limited amounts of information. Less observable traits (e.g., intelligence, analytic abilities) can also be assessed, but not with the same degree of reliability. In a typical study, naïve participants were exposed to three 10-second video clips of university teachers, and were asked to rate the targets on a series of 15 different personality traits (e.g., accepting, confident, honest, etc.). The participants’ ratings were significantly correlated with teaching evaluations made by students in the classes from which the videotaped information was taken. A total of 30 seconds worth of dynamic information enabled naïve perceivers to make effectiveness ratings that corresponded with students who had a full semester’s worth of information on which they could base their evaluations (Ambady & Rosenthal, 1993).

In a more direct application to consumer research, Ambady, Krabbenhoft, and Hogan (2006) demonstrated that naïve raters could accurately judge the effectiveness of salespeople based on three 20-second audio clips—with the semantic content filtered out. Participants listened to a total of 60 seconds worth of audio clips for each salesperson that effectively conveyed just the tone of the speaker’s voice. Based on this information, participants rated the salespeople on 19 traits (e.g., achievement-oriented, empathic, supportive, etc.). The traits were grouped into three composite variables—interpersonal, task-oriented, and anxious, and these composites were correlated with managers’ ratings of the salespeople. Participants’ interpersonal and anxiety ratings were significantly correlated (r 's > .50) with managers’ assessments of the salespeople’s effectiveness. In a second study, the content of the speech was retained in the 20-second audio clips. This time only participants’ interpersonal ratings were correlated with managers’ ratings of the sales people. Having more information (i.e., knowing *what* was said in study two, as opposed to knowing only *how* something was said in study one) actually impaired naïve judges’ ability to accurately evaluate the salespeople.

A good deal of research suggests that the ability to read thin slices of behavior is largely automatic (see Ambady, Bernieri, & Richeson, 2000). First, participants in thin slicing studies are unable to articulate (i.e., tend to be unaware of) the criteria they use to make judgments (Smith, Archer, & Costanzo, 1991); and asking participants explain the reasons for their judgments causes poorer performance (Ambady & Gray, 2002). Second, adding a cognitive load manipulation, which tends to disrupt controlled information processing, does not affect the accuracy of judgments based on thin slices of behavior (Ambady & Gray, 2002). Finally, increased effort, in the form of incentives, does not seem to improve performance (Bernieri & Gillis, 1995). Thus, the processes by which people make judgments based on thin slices of behavior tend to be consciously inaccessible and remain unaffected by attempts at either disruption or enhancement.

Because the participants in these studies seem to be unable to tell researchers how they make these judgments, the causal mechanism(s) underlying thin slice effects remain open to question. Ambady et al. (2000) have suggested that people are essentially relying on their stereotypes to make thin slice judgments. Consistent with the stereotyping account, Alba (2006) has suggested that halo effects may be at least partially behind the findings. People may be responding to physical features of the target, such as attractiveness, or baby-facedness (see Hassin & Trope, 2000). Peracchio and Luna (2006) suggest that affective responses might be driving thin slice effects. People may make judgments by relying on positive or negative feelings aroused by the thin slices of information (see Pham, Cohen, Pracejus, & Hughes, 2001; Pham & Avnet, 2005, for similar accounts of persuasion processes).

Another open question concerns conditions under which judgments based on thin slices are effective. Kardes (2006) applied Hogarth's (2001, 2005) learning structure model to analyze this problem, and suggested that thin slice judgments are most trustworthy when feedback quality is high (i.e., "frequent, prompt, and diagnostic," [p. 21]), and errors are consequential. These conditions enable people to learn very effectively, and make accurate judgments based on experience. When feedback quality is low, or when errors are relatively inconsequential, judgments based on thin slices of information are less likely to be accurate. This analysis, as well as further applications of the thin slicing research paradigm to consumer psychology, await empirical testing.

The thin slice paradigm presented by Ambady et al. (2006) may be useful for employers seeking to hire salespeople, but the general technique of thin slicing may be of use to others, as well, once boundary conditions are better understood. Spokespeople and product endorsers may be judged for credibility and trustworthiness using the thin slice technique (Ambady et al., 2006). Consumers and consumer researchers may use the technique to evaluate salespeople, lawyers, physicians, politicians, Web sites, brands, advertisements, customer service interactions, and so forth (Alba, 2006; Peracchio & Luna, 2006).

Applications of Implicit Memory. The literature on implicit memory, as it pertains to consumer psychology, is substantially smaller than that on subliminal perception and priming effects. Most of the implicit memory research in consumer psychology focuses on dissociations between implicit and explicit memory (with the notable exception of Lee, 2002, above), suggesting that explicit memory tests may not tell the full story with regard to brand awareness, or advertising efficacy.

A good example of implicit-explicit memory dissociation is in Jacoby, Kelley, Brown, and Jasechko's (1989) "false fame" effect. In the false fame effect, nonfamous names presented at time one are likely to be mistakenly identified as famous at time two, 24 hours later. Participants have no explicit recollection of the names, but their sense of familiarity with the previously presented nonfamous names leads them to attribute false fame. The same effect can emerge among brand names (Holden & Vanheule, 1999). Participants have no explicit awareness of having seen brand names previously,

but are likely to identify them as “real” brands. In a somewhat related vein, Butler and Berry (2001) found that previously shown brand names were more likely to be selected at time two, even when the product was different (e.g., brand X peaches at time one, brand X tomato sauce at time two). Importantly, this effect emerged among participants who showed no awareness of the primary aims of the study.

When examining memory for brands, Krishnan and Shapiro (1996) found that high-frequency brand names (e.g., Apple) are more likely to appear on word-stem completion measures than low-frequency brand names (e.g., Zenith). Further, semantic elaboration of brand names improved explicit memory over sensory elaboration, but showed no effect on implicit measures. Law and Braun (2000) used explicit and implicit measures to assess the impact of product placement on consumer memory and choice behavior. The explicit measures in this study were recognition and recall of products in a television show; the implicit measure was simply whether respondents chose a brand or not. Respondents showed better explicit memory for products that were central to the show, but centrality had little impact on the implicit choice measure. Also, products that were seen-only (as opposed to heard-only, and seen/heard) were most likely to be chosen on the implicit measure, but were the least likely to be recalled.

Acting Without Knowing: Awareness of Outcomes

Although there is a great deal of psychological research on behavior without awareness, the work on consumer behavior without awareness is limited, to say the least. The scientific study of behavior without awareness is a tricky business largely because conceptual and operational definitions of behavior without awareness are many and varied (see Adams, 1957; Frensch & Rüniger, 2003). People may be unaware of the behavior, itself (e.g., they may not realize they are tapping their foot). People may be unaware of some behavior’s relation to a contingent event (e.g., greater likelihood of buying as a function of having been asked a question about a product category). They may be unaware of physiological responses to stimuli (e.g., pupillary response, GSR). They may be unaware of goal activation, learning, and so forth.

It is clear enough that people cannot be aware of differential behavior as a function of subliminally presented stimuli. And it is generally assumed that people are unaware of subtle changes in their behavior as a result of priming manipulations. As noted above, when people become aware of these contingencies they tend to react against the primes. Still, it is uncertain whether people are consciously aware of their own tendencies toward reactance. The reactance, itself, could be operating automatically, outside of conscious awareness. A fuller discussion of implicit outcomes is beyond the scope of the present chapter, more deserving of a separate chapter. But it is also certainly an area ripe for future study.

CONCLUSIONS

Another unanswered research question is the extent to which implicit processes actually drive consumer behavior. Simonson (2005) argued that implicit cognition is unlikely to account for much of the variance in consumer choice and decision-making because most shopping environments are so cluttered with potentially priming stimuli that all primes would effectively wash one another out. Further, he argues that models of conscious, deliberative information processing and consumer choice (e.g., Bettman, Luce, & Payne, chapter 23, this volume) do a very good job of predicting behavior. He notes, “at this point it appears highly unlikely that the explanatory power offered by an analysis of unconscious influences will approach that provided by the assumption that choices are largely determined by conscious processing of task-relevant inputs” (p. 214).

While Simonson (2005) does not go so far as to suggest abandoning research on implicit consumer cognition (on the contrary, he is very encouraging), his comments are somewhat reminiscent of Mischel's (1968) assessment of personality research, and Wicker's (1969, 1971) critique of the attitude construct. Wicker's suggestion to consider abandoning the attitude construct for more fruitful areas of research was followed by a decade of enormous strides in understanding the relationship between attitudes and behavior (e.g., Ajzen & Fishbein, 1977; Fazio, Zanna, & Cooper, 1978; Fishbein, 1980; Fishbein & Ajzen, 1974). Now, over 35 years later, we are faced with a similar opportunity to conduct watershed research enabling a greater understanding of introspectively inaccessible cognitions and their influence on (consumer) behavior.

NOTE

1. An early criticism of the Vicary movie theater "study" was the claim that stimuli were presented at 1/3000 second. McConnell, Cutler, and McNeil (1958) expressed skepticism that 1/3000 second was "far faster than any previously reported stimulation" (p. 230).
